FEMSTAT PREFILL

(butoconazole nitrate) VAGINAL CREAM 2%

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

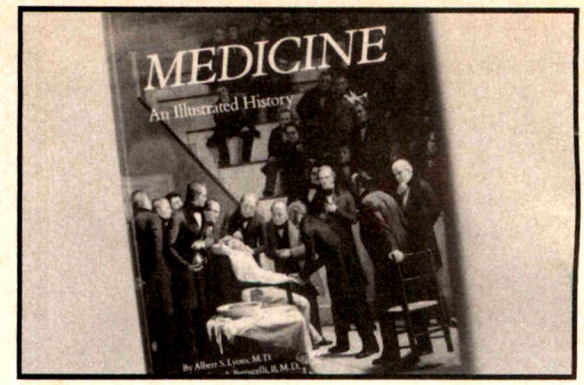
Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.



DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

MEDICINE: An Illustrated History

By Albert S. Lyons, M.D., F.A.C.S. and R. Joseph Petrucelli II, M.D.; with 14 contributors

This splendid survey will provide unending hours of pleasure. You'll enjoy relaxing with it after long hours in the office.

- brilliant color pictures review every dimension of medical history
- historical breakthroughs in medicine recorded with spellbinding prose
- timeless classic makes a splendid gift

1974. 618 pages, 1,020 illustrations including 250 in full color (Book Code: 03374) $42.95 (U.S.); $56.00 (Can.)

CEFOTAN® IM/IV
(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

Females: 0.9 × value for males

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

CLINICAL SECTION

Clinical Opinion

Drug prophylaxis for human immunodeficiency virus–infected pregnant women: Ethical considerations 1111

Howard L. Minkoff, MD, and Jonathan D. Moreno, PhD

Brooklyn, New York

The appropriateness of using new human immunodeficiency virus therapeutic agents, with unknown fetal effects, in the antepartum period is discussed.

Efficacy and safety considerations in women with uterine leiomyomas treated with gonadotropin-releasing hormone agonists: The estrogen threshold hypothesis 1114

Andrew J. Friedman, MD, Susan M. Lobel, MD, Mitchell S. Rein, MD, and Robert L. Barbieri, MD

Boston, Massachusetts

Treatment of women with uterine leiomyomas with gonadotropin-releasing hormone agonists may be useful preoperatively; the addition of low doses of steroid hormones to gonadotropin-releasing hormone agonist therapy may be useful for long-term medical treatment.

Clinical Articles

Contraception and ectopic pregnancy risk 1120

Adele L. Franks, MD, Valerie Beral, MB, BS, Willard Cates, Jr., MD, MPH, and Carol J. R. Hogue, PhD

Atlanta, Georgia

To clarify the relationship between contraception and ectopic pregnancy, we estimated incidence rates of ectopic pregnancy for a variety of contraceptive methods.

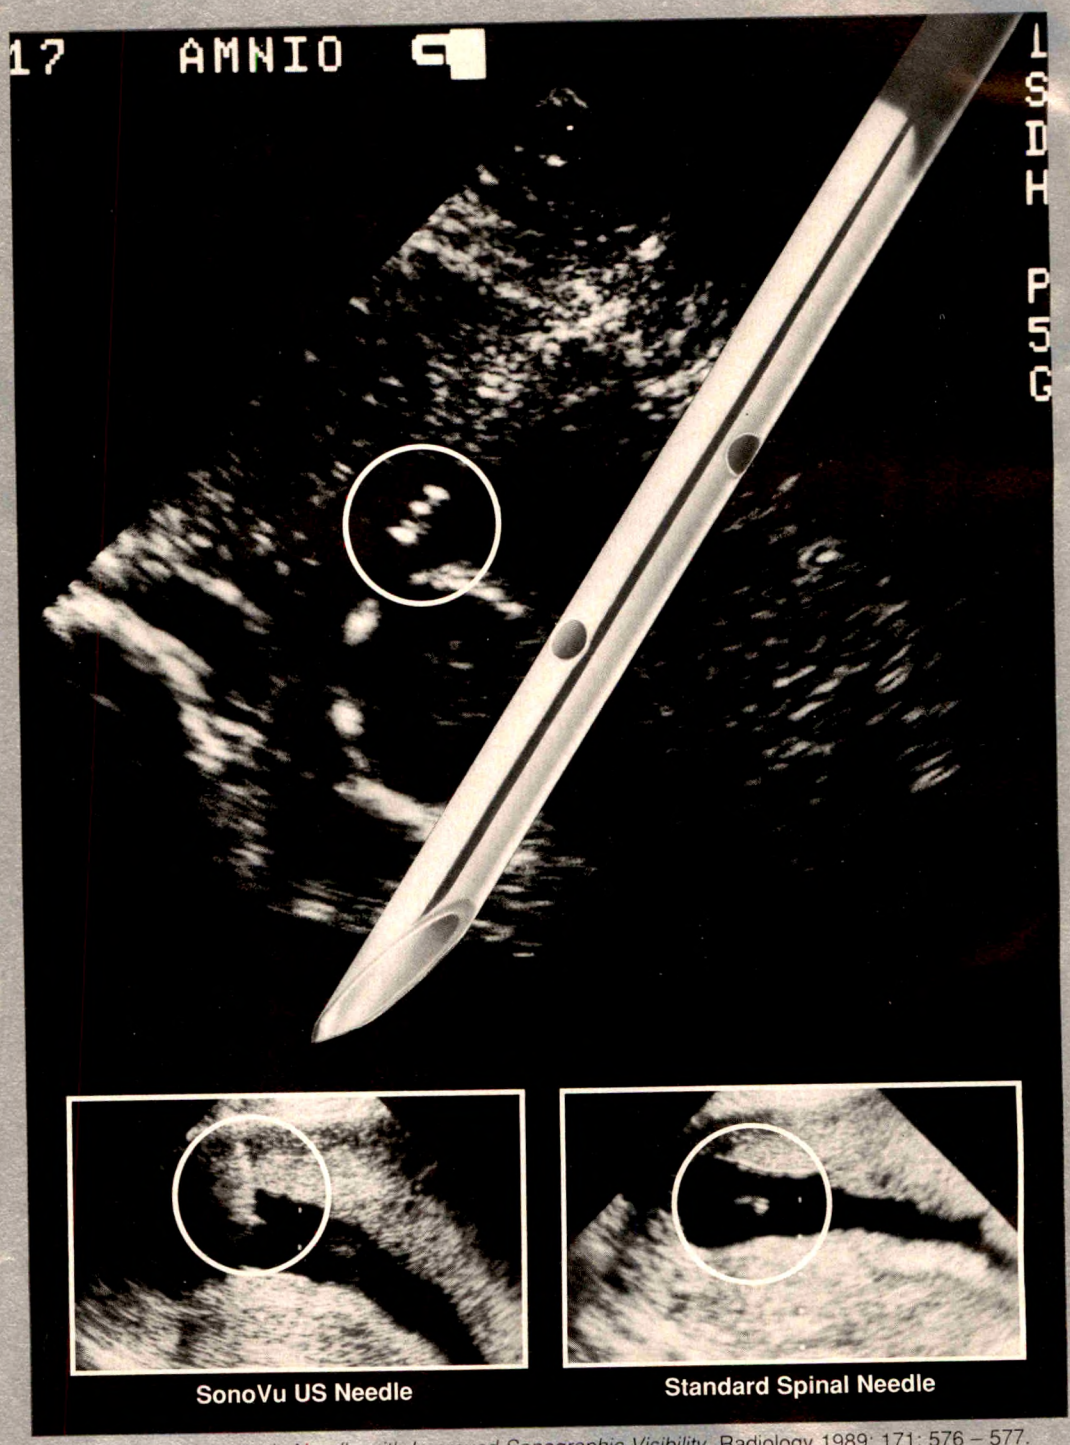
SonoVu US™—A visible improvement in ultrasound-guided aspiration.



The clearly visible bright echoes on the real-time sonogram below mark a breakthrough in accuracy and safety for fine-needle aspiration under ultrasound guidance.

SonoVu US, from E-Z-EM, is the first in a family of procedural needles designed specifically for enhanced ultrasound visualization.

Precisely formed 0.44 mm distal side holes on the cannula closely match the wavelength of ultrasound generated by a 3.5 MHz transducer. Uniform diffraction of the wave at each hole creates a highly visible echo on the US display.

The side holes also provide a significant increase in needle flow rate, and ensure free flow should the tip become occluded—often the case with spinal or chiba needles.

Developed for use in amniocentesis, the SonoVu design can offer similar benefits in such procedures as US-monitored biopsy and cyst aspiration. For more information on 20- and 22-gauge SonoVu US needles from E-Z-EM, call 1-800-544-4624.

For both the patient and the practitioner, E-Z-EM products set the standards for convenience, safety, and quality in:

- GI Radiology
- Interventional Radiology
- CT Scanning
- Ultrasound
- Magnetic Resonance Imaging
- Angiography
- CEA Immunostaining
- Radiation Oncology
- Patient Prepping

Calcium supplementation during pregnancy may reduce preterm delivery in high-risk populations 1124
Jose Villar, MD, and John T. Repke, MD
Bethesda and Baltimore, Maryland

Calcium supplementation in a high-risk population lowers blood pressure and may reduce the incidence of preeclampsia and prematurity.

The association of intrapartum asphyxia in the mature fetus with newborn behavior 1131
James A. Low, MD, Darwin W. Muir, PhD, Elizabeth A. Pater, RN, and E. Jane Karchmar, BA
Kingston, Ontario, Canada

Many newborns who have undergone an intrapartum asphyxial insult will not have evidence of central nervous system injury.

Sexually transmitted diseases and human immunodeficiency virus infection among women with pelvic inflammatory disease 1135
Bente Hoegsberg, MD, Ovadia Abulafia, MD, Alexander Sedlis, MD, Joseph Feldman, DrPH, Don DesJalais, PhD, Sheldon Landesman, MD, and Howard Minkoff, MD
Brooklyn and New York, New York

Women hospitalized with pelvic inflammatory disease and human immunodeficiency virus infection (15 of 110, 13.6%) had a hospital course similar to that of human immunodeficiency virus–negative women with a trend toward more operative interventions.

The effect of large uterine fibroids on urinary bladder function and symptoms 1139
Rami Langer, MD, Abraham Golan, MD, Menachem Neuman, MD, David Schneider, MD, Ian Bukovsky, MD, and Eliahu Caspi, MD
Zerifin, Israel

Bladder symptoms were lessened after reduction of uterine fibroids by gonadotropin-releasing hormone analogs.

THE PERMANENTE MEDICAL GROUP

NORTHERN CALIFORNIA

The Permanente Medical Group, the largest multispecialty group practice in the U.S., is undergoing explosive growth in its Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley. Our rapid increase in membership has created practice opportunities throughout the region for additional BC/BE Obstetricians and Gynecologists.

Our physician-managed group is part of the comprehensive Kaiser Permanente Medical Care Program. As a TPMG physician, you have access to the latest medical technology and resources, the support of colleagues in all subspecialties — and the opportunity to provide excellent health care without the burdens of managing a practice.

Join us in one of these facilities:

QUALITY

STABILITY

LEADERSHIP

GROWTH

SUPPORT

REWARDS

Richmond — Small, congenial clinic setting staffed by five physicians and five nurse practitioners with ready consultation for other services, including perinatology. Practice general OB/GYN, high-risk obstetrics and infertility. Expertise in colposcopy, laparoscopy, hysteroscopy and laser welcome. Resident teaching opportunities exist. Staff call at Kaiser Hospital in Oakland, shared with resident staff.

Oakland — Twenty physicians, 12 residents offer services in oncology, infertility, maternal-fetal medicine and a large ICN.

Redwood City — Specializes in family-centered maternity care; offers modern LDR rooms and full range of gynecological surgery. With ten physicians, 24-hour call is required three times each month. Beautiful Peninsula location, near San Francisco and the Pacific Ocean.

Stockton — Small four physician department in a new clinic building with new equipment, including laser. Stockton's lifestyle is affordable and attractive, offering recreational activities such as boating on the inland waterways. Centrally located, with mountains to the east and San Francisco Bay Area to the west.

Roseville — Eight physicians and two nurse practitioners in clinic setting. Patients are hospitalized for delivery and surgery in Sacramento where physicians take call for L&D and emergency about 5 times each month.

San Francisco — Full range of services including large high-risk, tertiary care OB service. Eighteen physicians, including GYN Oncologist. Residency program. Clinical research and academic teaching appointments available.

Sacramento — Growing metropolitan area between San Francisco Bay Area and Sierra Nevada mountains. Up-to-date facility with active staff of 14 and excellent residency program affiliated with the University of California at Davis. Flexible call averaging five shifts per month covers L&D, emergency room and inpatient services.

Pleasanton — Staffed by four physicians and three nurse practitioners, clinic provides general OB/GYN services, non-stress tests, ultrasound and cystoscopy. Consultant support, including a Perinatologist, readily available. Share call with staff of Walnut Creek Medical Center. Affiliated with the University of California at San Francisco as clinical instructors.

Fresno — Ground-floor opportunities in growing area for clinically-oriented individuals. Provide general OB/GYN; special interests encouraged. Planning new $26 million outpatient facility to accompany current medical office building. On call every fourth night and weekend. Local residency program at Valley Medical Center affiliated with the University of California at San Francisco. Teaching positions possible.

South San Francisco — Full service except L&D. Nine physicians, six nurse practitioners. On San Francisco Peninsula, 15 minutes from downtown.

KAISER PERMANENTE
Good People. Good Medicine.

TPMG offers many benefits: scheduled time off with cross-coverage provided by your colleagues, continuing education, malpractice insurance, a substantial retirement program and special arrangements for physicians transferring from established practice. For complete information, call or send CV to: The Permanente Medical Group, Inc., Richmond Prescott, M.D., Physician Recruitment Services, Dept. AOG-8348, 1814 Franklin, 4th Floor, Oakland, CA 94612. (800) 777-4912. EOE

The natural history of thrombocytopenia associated with preeclampsia 1142
Vern L. Katz, MD, John M. Thorp, Jr., MD, Lynda Rozas, BA, and Watson A. Bowes, Jr., MD
Chapel Hill, North Carolina

Thrombocytopenia associated with preeclampsia should resolve by postpartum day 4.

Continuing controversy in alloimmune thrombocytopenia: Fetal hyperimmunoglobulinemia fails to prevent thrombocytopenia 1144
Umberto Nicolini, MD, Yuen Tannirandorn, MD, Pedro Gonzalez, MD, Nicholas M. Fisk, MD, Jeremy Beacham, MSc, Elizabeth A. Letsky, MD, and Charles H. Rodeck, MD
London, England

Weekly in utero platelet transfusions are the only treatment that guarantees a safe fetal platelet count in cases of severe alloimmune thrombocytopenia.

Low fetal risks in pregnancies associated with idiopathic thrombocytopenic purpura 1147
Robert F. Burrows, MD, and John G. Kelton, MD
Hamilton, Ontario, Canada

Because only 3 of 61 infants of mothers with idiopathic thrombocytopenic purpura had a cord platelet count of $<50 \times 10^9$/L, maternal interventions that lead to maternal morbidity cannot be justified.

Laparoscopic ventrosuspensions 1151
Ann F. E. Yoong, MB, ChB
Merseyside, England

Laparoscopic ventrosuspension does not appear to be helpful in the management of deep dyspareunia or pelvic pain in women with retroverted uteri.

Pregnancy-induced hypertension and acute fatty liver of pregnancy: Atypical presentations 1154
Mark A. Brown, MD, George Passaris, MB, BS, and Mark A. Carlton, MB, BS
Sydney, Australia

Acute fatty liver of pregnancy and pregnancy-induced hypertension form a clinical continuum, and acute fatty liver of pregnancy may be seen with an isolated increase in hepatic alkaline phosphatase.

Vibroacoustic stimulation and fetal behavioral state in normal term human pregnancy 1156
Lawrence D. Devoe, MD, Cheri Murray, RN, David Faircloth, BS, and Edgard Ramos, MD
Augusta, Georgia

Vibroacoustic stimulation of normal term human fetuses resulted in alterations of behavioral state that appeared to be related to prestimulus behavioral state.

Successful conservative management of primary nonmetastatic cervical choriocarcinoma 1161
Avraham Ben-Chetrit, MD, Simcha Yagel, MD, Ilana Ariel, MD, David Zacut, MD, Shlomo Shimonovitz, MD, and Drorit Celnikier-Hochner, MD
Jerusalem, Israel

Primary cervical choriocarcinoma that occurred in a young patient who desired to preserve her fertility was successfully treated by local excision of the tumor followed by chemotherapy.

The prognostic significance of CA 125 half-life in patients with ovarian cancer who have received primary chemotherapy after surgical cytoreduction 1164
Verda J. Hunter, MD, Lee Daly, PA-C, Michael Helms, PhD, John T. Soper, MD, Andrew Berchuck, MD, Daniel L. Clarke-Pearson, MD, and Robert C. Bast, Jr., MD
Durham, North Carolina

A CA 125 half-life of <20 days during primary chemotherapy was associated with prolonged survival in patients with advanced epithelial ovarian cancer.

Management and outcomes of pregnancies complicated by human B19 parvovirus infection: A prospective study 1168
John F. Rodis, MD, Dorothy L. Quinn, MS, G. William Gary, Jr., MPH, DrPH, Larry J. Anderson, MD, Sally Rosengren, MD, Matthew L. Cartter, MD, Winston A. Campbell, MD, and Anthony M. Vintzileos, MD
Farmington and Hartford, Connecticut, and Atlanta, Georgia

Human B19 parvovirus infection in pregnancy is associated with a fetal loss rate of 5%.

Colon cancer in pregnancy with elevated maternal serum α-fetoprotein level at presentation 1172
Whitney Gonsoulin, MD, Brian Mason, MD, and Robert J. Carpenter, Jr., MD
Houston, Texas

A case of colon cancer first seen with elevated maternal serum α-fetoprotein levels in described.

Effects of hypertension on pregnancy monitoring and results 1173
Jack W. Lenox, MD, Valentine Uguru, MD, and Luis A. Cibils, MD
Chicago, Illinois

A 2-year review of patients with hypertension reveals that a six-base line in late decelerations is a good predictor of fetal outcome.

Spontaneous infarction of placental chorioangioma and associated regression of hydrops fetalis 1180
Cynthia Chazotte, MD, Barbara Girz, DO, Mordecai Koenigsberg, MD, and Wayne R. Cohen, MD
Bronx, New York

We report infarction of a large chorioangioma associated with regression of hydrops fetalis.

Contents

Ovarian pregnancy: A report of twenty cases in one institution 1182
Ariel Raziel, MD, Abraham Golan, MD, Mordechai Pansky, Md, Raphael Ron-El, MD, Ian Eukovsky, MD, and Eliahu Caspi, MD
Tel Aviv, Israel

Twenty cases of primary ovarian pregnancy diagnosed, treated, and followed up in one institution are presented; all the potentially fertile patients used an intrauterine contraceptive device.

Ultrasonographic detection of the second-trimester fetus with trisomy 18 and trisomy 21 1186
Norman Ginsberg, MD, Alan Cadkin, MD, Eugene Pergament, MD, PhD, and Yury Verlinsky, PhD
Chicago, Illinois

Biparietal diameter/femur length ratio and nuchal thickness are sensitive prenatal indicators of trisomy 18 and trisomy 21.

Second-trimester ultrasonography: Determinants of visualization of fetal anatomic structures 1191
Val Catanzarite, MD, PhD, and J. Gerald Quirk, MD, PhD
San Diego, California, and Little Rock, Arkansas

Maternal weight, gestational age, and maternal skin thickness were the major factors affecting visualization of fetal anatomic structures in a prospective series of 573 second-trimester ultrasonographic examinations.

Infertility and eating disorders 1196
Donna E. Stewart, MD, G. Erlick Robinson, MD, David S. Goldbloom, MD, and Charlene Wright, BSc
Toronto, Ontario, Canada

A previously undisclosed eating disorder (anorexia nervosa, bulimia nervosa, or eating disorder not otherwise specified) was discovered in 16.7% of consecutive infertility clinic patients.

Postpartum osteomyelitis caused by group B streptococcus 1200
K. Eerkowitz, MD, and R. McCaffrey, MD
New York, New York

Postpartum group B streptococcal osteomyelitis developed in a woman with vaginal colonization of group B streptococcus organisms and necessitated total hip replacement.

Antenatal spontaneous perforation of the extrahepatic biliary tree 1201
Syam Chilukuri, MD, Virgilio Bonet, MD, and Mason Cobb, MD
East Lansing, Michigan

Spontaneous perforation of the biliary duct can cause fetal ascites.

(Contents continued on page 12A)

Contents continued from page 11A

Antenatal diagnosis of molybdenum cofactor deficiency 1203
R. George F. Gray, PhD, Anne Green, MSc, Shishta Nadda Basu, MRCOG, Glyn Constantine, MD, Roy G. Condie, MD, Claude Dorche, PhD, Christine Vianey-Liaud, PhD, and Pierre Desjacques, PhD
Birmingham, United Kingdom, and Lyon, France

The assay of sulfite oxidase in chorionic villus tissue allows a rapid and early diagnosis of molybdenum cofactor deficiency.

Preoperative evaluation of serum CA 125, TAG 72, and CA 15-3 in patients with endometrial carcinoma 1204
John T. Soper, MD, Andrew Berchuck, MD, George J. Olt, MD, Andrew P. Soisson, MD, Daniel L. Clarke-Pearson, MD, and Robert C. Bast, Jr., MD
Durham, North Carolina

Tumor-associated antigen assays were not effective in detecting occult metastatic endometrial carcinoma.

Maternal serum α-fetoprotein levels in pregnancies complicated by diabetes: Implications for screening programs 1209
Alice O. Martin, PhD, Lisa M. Dempsey, MS, John Minogue, DMin, Kiang Liu, PhD, James Keller, MD, Ralph Tamura, MD, and Norbert Freinkel, MD
Chicago, Illinois

Maternal serum α-fetoprotein levels in diabetic patients are negatively associated with glycosylated hemoglobin values early in pregnancy and show a trend to be lower in the presence of early fetal growth delay.

High infectious morbidity in pregnant women with insulin-dependent diabetes: An understated complication 1217
Eric F. Stamler, MD, Maria L. Cruz, MD, Francis Mimouni, MD, Barak Rosenn, MD, Tariq Siddiqi, MD, Jane Khoury, MS, and Menachem Miodovnik, MD
Cincinnati, Ohio

Insulin-dependent diabetic pregnant patients are at significant risk for antepartum and postpartum infections; infectious morbidity may be associated with glycemic control.

The effect of race on the relationship between fetal death and altered fetal growth 1222
Richard Ferguson, MS, and Stephen A. Myers, DO
Chicago, Illinois

Outcome-derived risk assessment shows that 10th percentile birth weights do not consistently predict fetal death and that black fetuses are more sensitive to altered growth.

Effects of intravascular fetal blood transfusion on fetal intracardiac Doppler velocity waveforms 1231
Giuseppe Rizzo, MD, Kypros H. Nicolaides, MD, Domenico Arduini, MD, and Stuart Campbell, MD
Rome, Italy, and London, England

Intravascular fetal blood transfusion is associated with a temporary decrease in fetal cardiac output that is proportional to the degree of expansion in fetoplacental blood volume.

Contents

Human fetal foramen ovale flow velocity waveforms relative to behavioral states in normal term pregnancy 1239
Jim van Eyck, MD, PhD, Patricia A. Stewart, PhD, and Juriy W. Wladimiroff, MD, PhD
Rotterdam, The Netherlands

Averaged foramen ovale flow velocity increases during active sleep as compared with quiet sleep, suggesting increased right-to-left shunting at cardiac level.

Suppression of serum insulin level by diazoxide does not alter serum testosterone or sex hormone–binding globulin levels in healthy, nonobese women 1243
John E. Nestler, MD, Roshnara Singh, MD, Dennis W. Matt, PhD, John N. Clore, MD, and William G. Blackard, MD
Richmond, Virginia

Insulin suppression does not alter serum testosterone or sex hormone–binding globulin levels in nonobese, healthy women, suggesting that in these women insulin does not regulate testosterone metabolism.

Intrapartum uterine rupture and inflammatory bowel disease 1247
Ila M. Peterson, MD, and Bev Braak, MD
Kansas City, Missouri

This case report describes a previously undocumented association between steroid therapy for idiopathic inflammatory bowel disease and uterine rupture.

Maternal serum Down syndrome screening: Free β-protein is a more effective marker than human chorionic gonadotropin 1248
James N. Macri, PhD, Ramana V. Kasturi, BE, MS, David A. Krantz, BS, Edward J. Cook, PhD, Norman D. Moore, Jean A. Young, Kathleen Romero, BS, and John W. Larsen, Jr., MD
Carle Place, New York, and Washington, D.C.

Maternal serum screening for Down syndrome incorporating maternal age, α-fetoprotein, and the free β-protein of human chorionic gonadotropin can achieve 80% detection efficiency.

Prenatal diagnosis of congenital cytomegalovirus infection by virus isolation from amniotic fluid 1253
Carl P. Weiner, MD, and Charles Grose, MD
Iowa City, Iowa

Congenital cytomegalovirus infection was diagnosed prenatally by virus isolation from the amniotic fluid of two pregnant women.

Pelvimetry by magnetic resonance imaging in breech presentation 1256
Aren J. van Loon, MD, Albert Mantingh, MD, PhD, Cornelis J. P. Thijn, MD, PhD, and Eduard L. Mooyaart, MD, PhD
Groningen, The Netherlands

Pelvimetry with magnetic resonance imaging provides a safe and reliable method for pelvic assessment in breech presentation.

Intraamniotic infection in the very early phase of the second trimester 1261
Israel Goldstein, MD, Etan Z. Zimmer, MD, David Merzbach, PhD, Bezaleal A. Peretz, MD, and Etan Paldi, MD
Haifa, Israel

Intraamniotic infection can exist early in pregnancy, even with intact membranes, and in most cases without any clinical symptoms.

Placental histology in fetuses between 18 and 23 weeks' gestation with abnormal karyotype 1264
R. S. Kuhlmann, MD, PhD, A. L. Werner, MD, J. Abramowicz, MD, S. L. Warsof, MD, J. Arrington, RDMS, and D. L. Levy, MD
Norfolk, Virginia

Undervascularization of the placenta is seen in pregnancies complicated by abnormal karyotype.

Carbon dioxide laser energy disperses human papillomavirus deoxyribonucleic acid onto treatment fields 1271
Alex Ferenczy, MD, Christine Bergeron, MD, PhD, and Ralph M. Richart, MD
Montreal, Quebec, Canada, and New York, New York

Human papillomavirus deoxyribonucleic acid is present in anogenital skin that has been treated by carbon dioxide laser vaporization.

Emergency treatment with recombinant tissue plasminogen activator of pulmonary embolism in a pregnant woman with antithrombin III deficiency 1274
F. Baudo, MD, T. M. Caimi, R. Redaelli, PhD, A. M. Nosari, MD, M. Mauri, MD, G. Leonardi, MD, and F. deCataldo, MD
Milan, Italy

A 29-year-old pregnant woman with congenital antithrombin III deficiency and pulmonary embolism was successfully treated with recombinant tissue plasminogen activator without treatment-related complications to the newborn.

Collagen metabolism in gynecologic patients: Changes in the concentration of the aminoterminal propeptide of type III procollagen in serum 1276
Ulla Puistola, MD, PhD, Leila Risteli, MD, PhD, Juha Risteli, MD, PhD, and Antti Kauppila, MD
Oulu, Finland

Collagen metabolism measured with serum aminoterminal propeptide of type III procollagen is increased during the luteal phase of the cycle and in severe salpingo-oophoritis.

Current Development

Why all placentas should be examined by a pathologist in 1990 1282
Carolyn M. Salafia, MD, and Anthony M. Vintzileos, MD
Farmington, Connecticut

The clinical correlates of placental lesions and their clinical, as well as mediocolegal, implications for obstetric-neonatal practice are discussed.

Contents

BASIC SCIENCE SECTION

Role of vasopressin in mediation of fetal cardiovascular responses to acute hypoxia 1294

Kathleen M. Piacquadio, MD, Robert A. Brace, PhD, and Cecilia Y. Cheung, PhD

La Jolla, California

Arginine vasopressin may mediate in part the fetal heart rate response to acute severe hypoxia but does not appear to regulate fetal blood volume, arterial pressure, or venous pressure responses to hypoxia.

Autologous antibodies eluted from membrane fragments in human ovarian epithelial neoplastic effusions. III. Cytotoxic potential in vitro and characterization of antigen(s) 1301

William H. Kutteh, MD, PhD, Vicki V. Baker, MD, and George J. Doellgast, PhD

Birmingham, Alabama, and Winston-Salem, North Carolina

Autologous antibodies eluted from the cellular membrane fragments obtained from human ovarian neoplastic effusions are capable of complement-mediated cytotoxicity of human ovarian tumor cells.

Mechanism of action of interleukin-1β in increasing corticotropin-releasing factor and adrenocorticotropin hormone release from cultured human placental cells 1307

Felice Petraglia, MD, Gian Carlo Garuti, MD, Biagina De Ramundo, MD, Stefano Angioni, MD, Andrea R. Genazzani, MD, and Louise M. Bilezikjian, PhD

Modena, Italy, and La Jolla, California

The addition of interleukin-1β increases corticotropin-releasing factor and adrenocorticotropin hormone release from cultured placental cells, acting in part via a prostaglandin pathway.

Hypoxic acidemia, hyperviscosity, and maternal hypertension do not affect the umbilical arterial velocity waveform in fetal sheep 1313

Robert J. Morrow, MD, S. Lee Adamson, PhD, Shelley B. Bull, PhD, and J. W. Knox Ritchie, MD

Toronto, Ontario, Canada

Hypoxic acidosis, hyperviscosity, and maternal hypertension in fetal sheep do not cause umbilical arterial velocity waveform abnormalities similar to those of growth-restricted human fetuses.

A progesterone-induced blocking factor corrects high resorption rates in mice treated with antiprogesterone 1320

Julia Szekeres-Bartho, MD, PhD, G. Chaouat, MD, PhD, and R. Kinsky, DV, PhD

Pecs, Hungary, and Paris, France

Administration of preformed progesterone-induced blocking factor counteracted the abortive effect of progesterone receptor block.

Contents continued from page 15A

Effects of magnesium and isradipine on contractile activation induced by the thromboxane A_2 analog U46619 in human uteroplacental arteries in term pregnancy 1323
Kristjar Skajaa, MD, Danny Svane, MD, Karl-Erik Andersson, MD, PhD, and Axel Forman, MD, PhD
Arhus, Denmark, and Lund, Sweden

The thromboxane analog U46619 showed powerful vasoconstrictor effects in human maternal and fetal uteroplacental arteries; the responses could be inhibited by magnesium and the calcium antagonist isradipine.

The use of in situ hybridization to show human papillomavirus deoxyribonucleic acid in metastatic cancer cells within lymph nodes 1333
George Lewandowski, MD, Gregorio Delgado, MD, Robert W. Holloway, MD, Michael Farrell, PhD, A. Bennett Jenson, MD, and Wayne D. Lancaster, PhD
Washington, D.C.

Human papillomavirus type 16 deoxyribonucleic acid is shown within tumor metastases from cervical cancer primary lesions with in situ molecular hybridization.

Vasodilatory effects of nifedipine, methoxyverapamil, and sodium nitroprusside on contractile responses of the ewe uterine artery at term pregnancy 1337
Miguel Isla, DVM, PhD, and Donald C. Dyer, PhD
Ames, Iowa

The vasodilating effects of nifedipine, D-600, and sodium nitroprusside in uterine arteries from pregnancy are analyzed, and their possible use for preeclampsia treatment is discussed.

Fetal and maternal response to intravenous infusion of a thromboxane synthetase inhibitor 1345
John P. Cardin, Jr., MD, Michael G. Ross, MPH, MD, M. Gore Ervin, PhD, A. Victoria Schaffer, MD, Frank L. Douglas, PhD, MD, and John P. Simke
Torrance, California, and Summit, New Jersey

Administration of a thromboxane synthetase inhibitor to normotensive pregnant ewes resulted in maternal serum thromboxane B_2 suppression, unchanged maternal and fetal hemodynamics, and minimal placental drug transfer.

Long-term maternal-fetal exposure to high-low insulin concentrations alter liver but not brain insulin receptors 1350
S. Devaskar, MD, K. McMenamy, MD, L. Holtzclaw, BS, and F. Sadiq, MD
St. Louis, Missouri

Long-term exposure to high or low insulin concentrations alters the liver insulin receptor abundance but fails to affect brain insulin receptors in rat mothers and fetuses.

Venous and hepatic vascular responses to indomethacin and prostaglandin E_1 in the fetal lamb 1357
René P. Paulick, MD, Rebecka L. Meyers, MD, Colin D. Rudolph, MD, PhD, and Abraham M. Rudolph, MD
San Francisco, California

Prostaglandins have the effect of maintaining a modest degree of relaxation of the ductus venosus and hepatic microcirculation during fetal development.

"I was devastated when I found out I had genital herpes. What a relief when my doctor recommended a treatment program including Zovirax Ointment."

Zovirax® (acyclovir) Ointment 5% is an ideal complement to any treatment program for initial herpes genitalis. As clinical studies confirm, Zovirax Ointment 5% significantly lessens the duration of pain, shortens viral shedding, *and* speeds healing.[1-3]

Whenever the comfort of a topical antiviral medication is desired, prescribe Zovirax Ointment 5% for initial herpes genitalis. It suits her needs—just when she needs it most.

In initial herpes genitalis,

ZOVIRAX®
(ACYCLOVIR)
OINTMENT 5%
Antiviral Action... Proven Results

Please see brief summary of prescribing information on next page.

References: **1.** Lacey CJN, Meaden JD, Darville JM, et al. Topical acyclovir ointment in the treatment of genital herpes simplex virus infections. *Eur J Sex Trans Dis.* 1985;2:167-170. **2.** Thin RN, Nabarro JM, Parker JD, Fiddian AP. Topical acyclovir in the treatment of initial genital herpes. *Br J Vener Dis.* 1983;59:116-119. **3.** Corey L, Benedetti JK, Critchlow CW, et al. ZOVIRAX®
(ACYCLOVIR)
OINTMENT 5%

Before prescribing, please consult full package insert, a summary of which follows:

INDICATIONS AND USAGE: Zovirax (Acyclovir) Ointment 5% is indicated in the management of initial herpes genitalis and in limited nonlife-threatening mucocutaneous Herpes simplex virus infections in immunocompromised patients. In clinical trials of initial herpes genitalis, Zovirax Ointment 5% has shown a decrease in healing time and in some cases a decrease in duration of viral shedding and duration of pain. In studies in immunocompromised patients with mainly herpes labialis, there was a decrease in duration of viral shedding and a slight decrease in duration of pain.

By contrast, in studies of recurrent herpes genitalis and of herpes labialis in nonimmunocompromised patients, there was no evidence of clinical benefit; there was some decrease in duration of viral shedding.

Diagnosis: Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[1] Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases.

CONTRAINDICATIONS: Zovirax Ointment 5% is contraindicated for patients who develop hypersensitivity or chemical intolerance to the components of the formulation.

WARNINGS: Zovirax Ointment 5% is intended for cutaneous use only and should not be used in the eye.

PRECAUTIONS:

General: The recommended dosage, frequency of applications, and length of treatment should not be exceeded (see DOSAGE AND ADMINISTRATION). There exist no data which demonstrate that the use of Zovirax Ointment 5% will either prevent transmission of infection to other persons or prevent recurrent infections when applied in the absence of signs and symptoms. Zovirax Ointment 5% should not be used for the prevention of recurrent HSV infections. Although clinically significant viral resistance associated with the use of Zovirax Ointment 5% has not been observed, this possibility exists.

Drug Interactions: Clinical experience has identified no interactions resulting from topical or systemic administration of other drugs concomitantly with Zovirax Ointment 5%.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg/day given by gavage. These studies showed no statistically significant difference in the incidence of benign and malignant tumors produced in drug-treated as compared to control animals, nor did acyclovir induce the occurrence of tumors earlier in drug-treated animals as compared to controls. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive response for mutagenicity and chromosomal damage occurred, but only at concentrations at least 1000 times the plasma levels achieved in man following topical application.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day or in rats at subcutaneous doses up to 25 mg/kg/day. In rabbits given a high dose of acyclovir (50 mg/kg/day, s.c.), there was a statistically significant decrease in implantation efficiency.

Pregnancy: *Teratogenic Effects*. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c. and i.v.) or in standard tests in the rat (50 mg/kg/day, s.c.). In a non-standard test in rats, fetal abnormalities, such as head and tail anomalies, were observed following subcutaneous administration of acyclovir at very high doses associated with toxicity to the maternal rat. The clinical relevance of these findings is uncertain.[2] There are no adequate and well-controlled studies in pregnant women. Acyclovir should not be used during pregnancy unless the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax is administered to a nursing woman.

ADVERSE REACTIONS: Because ulcerated genital lesions are characteristically tender and sensitive to any contact or manipulation, patients may experience discomfort upon application of ointment. In the controlled clinical trials, mild pain (including transient burning and stinging) was reported by 103 (28.3%) of 364 patients treated with acyclovir and by 115 (31.1%) of 370 patients treated with placebo; treatment was discontinued in 2 of these patients. Other local reactions among acyclovir-treated patients included pruritus in 15 (4.1%), rash in 1 (0.3%) and vulvitis in 1 (0.3%). Among the placebo-treated patients, pruritus was reported by 17 (4.6%) and rash by 1 (0.3%).

In all studies, there was no significant difference between the drug and placebo group in the rate or type of reported adverse reactions nor were there any differences in abnormal clinical laboratory findings.

OVERDOSAGE: Overdosage by topical application of Zovirax Ointment 5% is unlikely because of limited transcutaneous absorption (see Clinical Pharmacology).

DOSAGE AND ADMINISTRATION: Apply sufficient quantity to adequately cover all lesions every 3 hours 6 times per day for 7 days. The dose size per application will vary depending upon the total lesion area but should approximate a one-half inch ribbon of ointment per 4 square inches of surface area. A finger cot or rubber glove should be used when applying Zovirax to prevent autoinoculation of other body sites and transmission of infection to other persons. **Therapy should be initiated as early as possible following onset of signs and symptoms.**

HOW SUPPLIED: Zovirax Ointment 5% is supplied in 15 g tubes (NDC 0081-0993-94) and 3 g tubes (NDC 0081-0993-41). Each gram contains 50 mg acyclovir in a polyethylene glycol base. Store at 15°-25°C (59°-77°F) in a dry place.

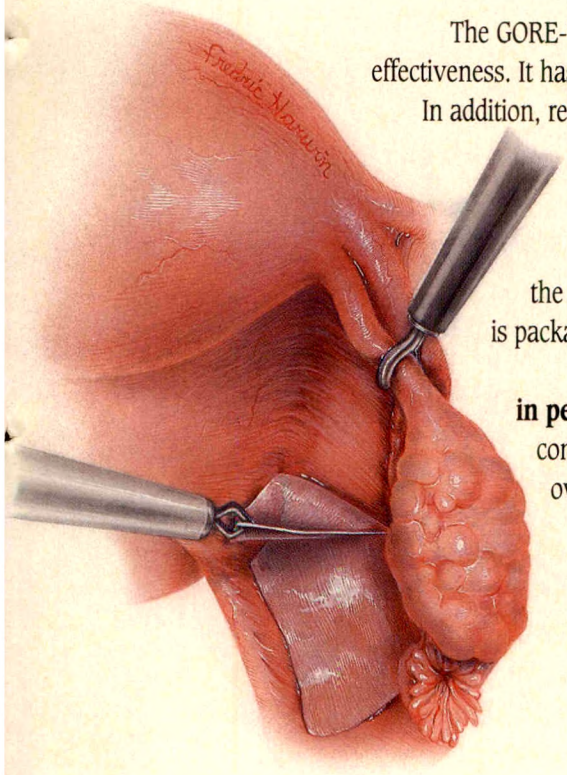
in Adhesions...

...The GORE-TEX® Surgical Membrane
The Choice in Peritoneal Reconstruction



Successful peritoneal reconstruction requires dependable measures to minimize adhesion reformation following adhesiolysis. The invariant performance of the GORE-TEX Surgical Membrane aids in producing consistent results.

Performance by Design

Composed of the inert biomaterial, expanded polytetrafluoroethylene (e-PTFE), the GORE-TEX Surgical Membrane limits tissue attachment with an extremely small pore size. The nonabsorbable material is a physical barrier which minimizes adhesion between adjacent tissues.

Proven and Established

The GORE-TEX Surgical Membrane has a long record of safety and effectiveness. It has demonstrated reliability among cardiac surgeons for more than 14 years. In addition, recent use in a multi-center clinical study has substantiated safety and shown invariant performance in peritoneal repair.

Convenient

Available in specific configurations tailored for pelvic adhesion reduction, the GORE-TEX Surgical Membrane – *Configured for Peritoneal Reconstruction* is packaged sterile and **can be resterilized**.

Choose the GORE-TEX Surgical Membrane for invariant performance in peritoneal reconstruction. To receive further information or to consult an application specialist, call **800-437-8181**. For orders and overnight delivery 24 hours a day, please call **800-528-8763**.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the

Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number are allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Abstracts are not acceptable as numbered references.

Illustrations and tables. Illustrations and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice.

A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in

sequence after the references. Titles should be included in the legend, *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words [excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"]. The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy photographic prints are submitted, properly numbered and labeled on the back of each print.
—Three sets of computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title
—Author(s) name(s) and highest academic degree(s)
—City(ies), state(s), and country other than U.S. in which the study was conducted are given
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated
—Acknowledgment of financial support is cited
—Name, address, and business and home telephone numbers of author to whom requests for reprints are to be sent
—Reprints will not be available. This has been stated on the title page
—Since the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, and business and home telephone numbers have been added
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a caption and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in sequence in the text.

Figures

—Are numbered in Arabic numerals and are cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Abstracts, personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted and the signed approval is enclosed.

ESTRACE® (17β-estradiol)

TABLETS, 1 mg and 2 mg VAGINAL CREAM, 0.01%

WARNING

1. **ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.** Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. **ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.** The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1,000 exposures. Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects. One case control study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed *in utero* to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1,000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If Estrace is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation.

Indications: *Tablets:* Moderate to severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.); atrophic vaginitis; kraurosis vulvae; female hypogonadism; female castration; primary ovarian failure; breast cancer (for palliation only) in appropriately selected women and men with metastatic disease; prostatic carcinoma–palliative therapy of advanced disease. *Cream:* Estrace Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae. ESTRACE® HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Contraindications: *Estrogens should not be used in women (or men) with any of the following conditions:* Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease; known or suspected estrogen-dependent neoplasia; known or suspected pregnancy (See Boxed Warning); undiagnosed abnormal genital bleeding; active thrombophlebitis or thromboembolic disorders; a past history of thrombophlebitis, thrombosis or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

Warnings: *Induction of malignant neoplasms.* Long term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. There is now evidence that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning). At the present time there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast, although a recent long-term follow-up of a single physician's practice has raised this possibility. Because of the animal data there is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. *Gallbladder disease.* A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens, similar to the 2-fold increase previously noted in users of oral contraceptives. In the case of oral contraceptives, the increased risk appeared after two years of use. *Effects similar to those caused by estrogen-progestogen oral contraceptives.* There are several serious adverse effects of oral contraceptives, most of which have not, up to now, been documented as consequences of postmenopausal estrogen therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women. It would be expected that the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement are more likely to result in these adverse effects, and, in fact, it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. *Thromboembolic disease.* It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found, this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore, estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used (except in treatment of malignancy) in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed. Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk. *Hepatic adenoma.* Hepatic adenomas appear to be associated with the use of oral contraceptives. Although rare, these may rupture and may cause death through intraabdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations but should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The relationship of this malignancy to these drugs is not known at this time. *Elevated blood pressure.* Increased blood pressure is not uncommon in women using oral contraceptives. There is now a report that this may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used. *Glucose tolerance.* A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen. *Hypercalcemia.* Administration of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

Precautions: *General Precautions.* A complete medical and family history should be taken prior to the initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Fluid retention–Because estrogens may cause some degree of fluid retention, conditions which might be influenced by this factor such as epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed. Preexisting uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving estrogen-containing oral contraceptive therapy. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens may be poorly metabolized in patients with impaired liver function and they should be administered with caution in such patients. Because estrogens influence the metabolism of calcium and phosphorus, they should be used with caution in patients with metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency. Because of the effects of estrogens on epiphyseal closure, they should be used judiciously in young patients in whom bone growth is not complete. Certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following similar changes may be expected with larger doses of estrogen: increased sulfobromophthalein retention; increased prothrombin and factors VII and VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability; increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by volume, or T4 by radioimmunoassay; free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered; impaired glucose tolerance; decreased pregnanediol excretion; reduced response to metyrapone test; reduced serum folate concentration; increased serum triglyceride and phospholipid concentration. *Pregnancy Category X.* See Contraindications and Boxed Warning. *Nursing Mothers.* As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk. Estrace 2 mg tablets contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Adverse Reactions: (See Warnings regarding induction of neoplasia, adverse effects on the fetus, increased incidence of gallbladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions have been reported with estrogenic therapy, including oral contraceptives: *Genitourinary system*–Breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis; change in cervical eversion and in degree of cervical secretion; cystitis-like syndrome. *Breast*–tenderness, enlargement, secretion. *Gastrointestinal*–Nausea, vomiting; abdominal cramps, bloating, cholestatic jaundice. *Skin*–Chloasma or melasma which may persist when drug is discontinued; erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism. *Eyes*–Steepening of corneal curvature; intolerance to contact lenses. *CNS*–Headache, migraine, dizziness; mental depression; chorea. *Miscellaneous*–Increase or decrease in weight, reduced carbohydrate tolerance; aggravation of porphyria, edema, changes in libido.

Overdosage: Numerous reports of ingestion of large doses of estrogen-containing oral contraceptives by young children indicate that serious ill effects do not occur. Overdosage of estrogen may cause nausea, and withdrawal bleeding may occur in females.

How Supplied: Estrace 1 mg; lavender scored tablets–*NDC* 0087-0755-01-Bottles of 100; *NDC* 0087-0755-44-Compacts of 25. Estrace 2 mg; turquoise scored tablets–*NDC* 0087-0756-01-Bottles of 100; *NDC* 0087-0756-44-Compacts of 25. Estrace Vaginal Cream; *NDC* 0087-0754-42 42.5 g Tube with one applicator calibrated for delivery of 1, 2, 3 or 4g.

American Journal of Obstetrics and Gynecology

Founded in 1920

volume 163 *number* 4 *part* 1 OCTOBER 1990

EDITORIAL

The first seventy years

The AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY will celebrate its seventieth year in October 1990.

The lineage of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY comes from the *American Journal of Obstetrics and Diseases of Women and Children,* founded in 1869 and published successfully for 50 years, then succumbing to financial difficulties. The AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY began from that journal a few months later, with a new publisher, The C. V. Mosby Company, now Mosby–Year Book, Inc. The name changed slightly but the previous editor, Dr. George Kosmak, continued and spent 33 additional years editing the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY. When the JOURNAL began in 1920, the intent was to publish original communications, research, and special society transactions.

There has been a continuity of editors during the past seventy years. As a matter of fact, there have been only eight editors during this period of time, and they are as follows:

George W. Kosmak	1920-1953	(33 years)
Hugo Ehrenfest	1935-1942	(7 years)
Howard C. Taylor, Jr.	1953-1969	(16 years)
William J. Dieckmann	1953-1964	(11 years)
Allan C. Barnes	1958-1971	(13 years)
John I. Brewer	1958-1990	(32 years)
Edward J. Quilligan	1971-present	(19 years)
Frederick P. Zuspan	1971-present	(19 years)

Also, many of the editors served as associate editors before their tenure as editor.

How appropriate it is today to appreciate the editorial from the *American Journal of Obstetrics and Diseases of Women and Children* published in 1869, which says the following:

> There has probably been no period in which Obstetrics and Gynecology have engaged more attention both at home and abroad than they do at the present time, and the tremendous strides which the above branches of the science of medicine have made within the last few years have necessarily given us a literature of the same, which equals, if it does not excel that of any other branch. It is to be regretted, however, that the practical part of our profession is so arduous, and the fulfillment of its duties consumes so much time, that weeks, and doubtless in many instances even months, elapse before we become familiar with the latest and accepted views and teachings of those who are recognized as authorities on their subject; a few moments, however, given to the perusal of a Journal will often supply the place of original works, by giving extracts, reviews, and a general synopsis of the same, while its original communications, when carefully selected, will likewise afford valuable and practical information.
>
> E. Noeggerath, MD, and B. F. Dawson, MD, Editors
> *American Journal of Obstetrics and Diseases of Women and Children,* 1869

The JOURNAL has changed and evolved during these past seventy years in an effort to constantly provide readers with current facts in the area of reproductive medicine. Our sections in the JOURNAL have been divided into Clinical and Basic Science areas. The present trend of investigation tends to be toward a narrow but more intense arena in the reproductive sciences, namely, those involved with maternal-fetal medicine, reproductive endocrinology-infertility, gynecologic oncology, and general obstetrics-gynecology. The Editors and Publisher believe that information and discoveries should be quickly and accurately communicated to the reader. During the past four years our publication time, from the date of acceptance, has been 4.7 months.

Last year we published 629 articles in twelve issues of the JOURNAL. Seventy-two percent of those articles originated in the United States, nine percent in Canada, and nineteen percent from abroad. This distribution has remained relatively constant for the last four years.

The majority of our articles are regular, nonsociety articles, but other categories include society articles, case reports, brief communications, and Current Investigation, Current Development, and Clinical Opinion sections. Letters to the Editors totaled 239, of which 202 were accepted.

Statistics, 1989

Category	*Processed*	*Accepted*	*Percent*
Regular nonsociety	1431	326	23
Society	217	197	91
Case reports and brief communications	245	86	35
Current Investigation	4	2	50
Current Development	8	6	76
Clinical Opinion	29	16	55

The distribution of articles is divided among Fetus-Placenta-Newborn 36%, Gynecology 25%, Obstetrics 38%, Ethics and Education 1%, Clinical or Clinical Investigation 83%, and Basic Science 17%.

Each regular article in the JOURNAL is approximated at 5 pages whereas case reports and brief communications are 2 pages.

A formal peer review process for all manuscripts was established many years ago. Society articles, as well as regular articles, all receive peer review. The consultants are qualified authorities in their respective fields, and without them the JOURNAL would not be of the quality that it is today. We extend a heart-filled thanks to all who have participated in this arduous and very important task of peer review.

Evolution of the JOURNAL has included a change from a monthly publication (for 42 years, from 1920 until 1962) to a semi-monthly publication. The editorial advisory board and others recommended that we go back to once-a-month publication in 1986. In 1985 we developed a new format separating Clinical and Basic Science articles but still maintained the three classifications of Obstetrics, Gynecology, and Fetus-Placenta-Newborn.

The Editors and Publisher are proud of the quality of this JOURNAL, but we also feel that the editorial advisory board and its peer consultants have played an instrumental role in the achievements of the JOURNAL to the heights it now enjoys. It is in the top two percent of more than 4000 journals published in the world today. The AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY ranks first among obstetrics and gynecology journals in the *Science Citation Index.*

Beginning with the next volume another change will take place in the editorial makeup of the JOURNAL. Dr. John I. Brewer will become an emeritus editor, and Dr. Quilligan and Dr. Zuspan will assume the editor-in-chief role. Two associate editors, Dr. Steven Gabbe and Dr. Moon Kim, will assist Dr. Zuspan. Another two associate editors, Dr. Thomas Garite and Dr. Alberto Manetta, will assist Dr. Quilligan. This is a brief capsule of the first 70 years of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY. We thank everyone who has played a role in its success.

The Editors and Mosby–Year Book, Inc.

Clinical Opinion

Drug prophylaxis for human immunodeficiency virus–infected pregnant women: Ethical considerations

Howard L. Minkoff, MD,[a] and Jonathan D. Moreno, PhD[b]
Brooklyn, New York

More than 5000 women infected with human immunodeficiency virus give birth annually in the United States. Many of these women are offered human immunodeficiency virus tests in prenatal settings. One of the incentives for them to be tested is access to medications that have been shown to prolong disease-free intervals in nonpregnant human immunodeficiency virus–infected individuals. However, the use of those medications during pregnancy has not been well studied and some have cautioned against their prenatal use. Thus consideration of these agents may be deferred by some clinicians until the postpartum period. In this article we argue that the availability of such agents should be disclosed to women who are seropositive for human immunodeficiency virus as part of the informed consent process. (AM J OBSTET GYNECOL 1990;163:1111-4.)

Key words: Human immunodeficiency virus, pregnancy, pentamidine

Pregnancies complicated by human immunodeficiency virus (HIV) infections are becoming increasingly common in many parts of that United States. A number of health agencies have instituted anonymous surveillance programs that have provided estimates of the seroprevalence of HIV among pregnant women.[1-3] In New York State, for example, which has one of the most extensive programs, 0.66% of neonates are born with maternal HIV antibody in the blood.[1] Similar programs in Massachusetts have revealed that 0.75% of neonates in urban hospitals are HIV seropositive.[2] Thus it is clear that several thousand HIV-infected women give birth annually in the United States. Coincident with the recognition of this problem prenatal HIV counseling and testing programs have been recommended by a variety of agencies (e.g., Centers for Disease Control [CDC],[4] American College of Obstetricians and Gynecologists[5]) and have been instituted in many prenatal centers.[6, 7]

One of the incentives for women to undergo testing has been the widely publicized benefits of zidovidine for asymptomatic HIV-infected individuals with CD4 counts <500 mm^3. Zidovudine, along with agents used for *Pneumocystis carinii* pneumonia prophylaxis (e.g., aerosol pentamidine), holds the hope of prolonged disease-free intervals for infected individuals. Since a common site of testing has been prenatal clinics and since experience with these agents in pregnancy is lacking, obstetricians are not infrequently faced with the dilemma of choosing whether appropriate prenatal care of infected women involves the use of, or even discussions regarding the use of, these drugs.

Although these agents are reported to be life-extending, the CDC still states that the use of pentamidine prophylaxis in pregnancy, for example, "is inadvisable."[8] When some clinicians are confronted with this fairly strong caveat, it is probable that they will withdraw the drug from their patient's consideration until delivery has occurred. The appropriateness of that approach has not been formally considered. In this article we argue that the availability of HIV agents such as pentamidine should be disclosed to HIV-seropositive pregnant women as part of the informed consent process.

In general physicians caring for pregnant patients counsel them about the risks, benefits, and uncertainties of various therapeutic options. Patients are then free to pursue what they perceive to be the best interest of their fetuses and themselves. In the case of HIV disease this counseling includes discussions about the significance of HIV disease in pregnancy, the risks of perinatal transmission of HIV, and the availability of all reproductive options. What is less clear is whether

6/1/21552

a physician's perception of excessive fetal risk should ever override the mother's ability to gain access to medication and, if so, under what circumstances. Under circumstances in which the mother's life is threatened, physician's deference to fetal considerations protects the fetus at a price of imposing grave risk to the woman and constitutes a potentially dangerous assault on autonomy. Conversely, a physician's refusal to provide known teratogenic agents whose sole benefit would be cosmetic, would seem appropriate and ethical even if the patient was never informed of the agent's existence and potential benefits.

Newer agents used for HIV disease would not appear *a priori* to be at either of the cited extremes. Although the drugs can be life-extending, there is no evidence that deferring therapy with these agents for a few months would make a substantive difference in the natural history of the disease when CD4 counts start in the upper range at which prophylaxis is recommended (400 to 500 mm^3). The risks to the fetus are also unclear. Aerosol pentamidine achieves extremely low blood levels but may concentrate in tissues.[9] Zidovidine has not proved harmful in some lower animal models, has much greater affinity for ribonucleic acid than deoxyribonucleic acid,[10] but can have serious side effects in adults. Thus enough ambiguity about risks and benefits exists to warrant formal consideration of the proper framework for their use in pregnancy and for the proper repository of ultimate responsibility for instituting therapy.

To follow an application of informed consent doctrine to decision making in pregnancy, we turn to several specific issues concerning the counseling and treatment of fertile HIV-seropositive women. Because women with or at risk for HIV tend to be in an especially precarious social and financial position, we conclude by reiterating the importance of shared decision making as a model to guide physicians who work with these patients.

Informed consent and decision making in pregnancy

The doctrine of informed consent provides that physicians must disclose to competent adult patients all information about alternative therapies, including nontreatment, that would be material to an informed choice. This standard requires disclosure of all information that the patient cannot be reasonably expected to know. However, there is no definitive guidance for physicians concerning what degree or sorts of risk warrant nondisclosure. The courts have articulated two standards for disclosure of risks and alternatives: an "objective" test and a "subjective" test.[11] The objective test can be expressed as that which a reasonable, prudent person would decide under the circumstances, while the subjective test is that which an individual patient would consider a significant risk.

Pregnancy poses the additional complexity that another individual, the fetus, has weighty interests that are directly involved and must be taken into account. Certainly this is the case with regard to the fetus that is intended to be brought to term. Some will even consider the fetus virtually a patient in light of new technologies that can both test and treat some fetal conditions. When patients cannot speak for themselves, it is accepted that a surrogate decision maker should be identified. In spite of some highly publicized but eccentric court decisions,[12] it is customary to accept the mother as the appropriate representative of fetal interest, but her role in this process can be effective only to the extent that risks and alternatives are disclosed to her.

The objective test is clearly more restrictive than the subjective test in the sense that it requires that the construing of risk be "reasonable." Nevertheless, even with that standard the availability of HIV therapeutics such as pentamidine prophylaxis ethically should be disclosed to pregnant women with CD4 counts in the prescribed range. One who chose this therapy under these circumstances would not be making a choice that is clearly unreasonable or imprudent; although the life-extending benefits of the therapy might not be lost if it is deferred, there is no basis for certainty in that regard. Furthermore, risks presented to the fetus are also, at this time, highly uncertain.

By contrast, there are some therapeutic agents the selection of which during pregnancy would clearly be unreasonable and imprudent. An example is thalidomide, which presents a high teratogenic risk with the relatively slight benefit of increased maternal comfort. According to the objective test physicians are under no ethical obligation to disclose the availability of such agents.

Our conclusion is that the availability of pentamidine should be disclosed to pregnant women who are asymptomatic for HIV but whose CD4 counts would in principle warrant this prophylaxis. This position is consistent with the CDC's characterization of its use as "inadvisable." While a pregnant patient's decision to use the agent may not be the "best" decision in the sense that she should clearly be advised to do so, there is sufficient ambiguity to warrant respecting the patient's *prima facie* right to make an individual determination that is based on her own values. In other words, the question of whether a certain therapy is advisable must be distinguished from the question of whether its existence as an alternative should be disclosed. Thus it is of some concern that current CDC recommendations go on to state: "Prophylaxis can then be considered for use in the postpartum period."[8] The implication that

even "consideration" before delivery is ill-advised is not compatible with the collaborative process that should characterize clinical decision making.

The context for discussion of HIV agents with pregnant women

The disclosure and possible use of medications for the treatment of HIV in a pregnant woman will of course be closely bound up with a number of other decisions that will have to be made in the course of the pregnancy, including whether the woman should become pregnant, whether abortion is advisable should she become pregnant, and how decisions will be made for the child if he or she is born HIV-positive and if acquired immunodeficiency syndrome actually develops. Knowledge of the availability of aerosolized pentamidine and its potential risks could, for example, affect a decision to become pregnant or to continue a pregnancy. Similarly, knowledge of risks to the fetus could help impress on the mother the importance of identifying a surrogate decision maker for her future child should she be incapacitated.

The questions whether a women with or at risk for HIV should be counseled not to become pregnant or whether, once pregnant, she should be advised to terminate the pregnancy are beyond the scope of this article. However, it seems worth noting that there is nothing about HIV disease per se that requires the adoption of a position different from that in counseling any women with a life-threatening disease that poses some risk to a fetus. Health care providers are no less susceptible than anyone else to taking HIV as somehow *sui generis*.

Physician-patient relations

Underlying the particular question about the use of HIV therapeutics in pregnancy is a larger issue about relations between physicians and patients. The language of "disclosure" comports with the ancient Hippocratic tradition of secrecy and silence, one in which physicians hold the keys to sacred knowledge that in the hands of the uninitiated would present untold dangers. In an era when medical and surgical interventions harmed as often as they healed, there was some warrant for this attitude. But the growth of scientific medicine provides patients with more or less predictable options for their lives. Under these conditions there has been greater appreciation, at least rhetorically, that patients must be permitted to involve themselves as deeply as they wish in assessing and selecting their alternatives. The President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research characterized this process as one of "shared decision making."[13] Yet in both the clinics and the courts it remains more a goal than a reality.

The implementation of collaborative decision making requires that doctors engage in an open dialogue with their patients, which is a significant departure from the profession's tradition and is not a skill usually imparted in medical school.[14]

The familiar yet unique dilemma posed by the treatment of a pregnant patient is the possibility that maternal and fetal interests will conflict. The physician may feel the need to balance competing risks and benefits for two patients with few guidelines other than those derived from his or her own values. As long as the clinician's focus remains on the question of what should and should not be disclosed, his or her potentially conflicting roles as obstetrician and fetal advocate will persist. The treatment of HIV-infected women in pregnancy with unfamiliar medications should instead present an opportunity to work with patients to identify acceptable levels of risk. Physicians are under no moral obligation to pursue a course of treatment they regard as unconscionable, but in most instances they may find that an open discussion facilitates a result that is more acceptable than they had anticipated. At least the moral burden of the decision need not and should not rest entirely on the physician's shoulders.

The demography of HIV infections in pregnancy demands that physicians treating pregnant patients be particularly aware of this point. Currently almost 80% of HIV-infected infants have been born to black or Hispanic women, the vast majority of whom are poor and underinsured or uninsured. These patient characteristics, together with the clinical situations in which the patients are often seen, can combine to lessen the likelihood that they will be engaged by physicians in a joint endeavor to make decisions about their lives and that of their future children. Certainly there are instances in which providing a particular medical treatment may clearly be inadvisable. When ambiguity exists, however, informing a mother and empowering her to act on behalf of her fetus and herself "safeguards the autonomy of both parties."[14] Anything less denies the mother's rightful primacy both as fetal champion and as the focus of her physician's concern.

Efficacy and safety considerations in women with uterine leiomyomas treated with gonadotropin-releasing hormone agonists: The estrogen threshold hypothesis

Andrew J. Friedman, MD, Susan M. Lobel, MD, Mitchell S. Rein, MD, and Robert L. Barbieri, MD

Boston, Massachusetts

Gonadotropin-releasing hormone agonists induce a reversible hypogonadotropic hypogonadal environment. Leiomyomas are common, estrogen-sensitive, benign neoplasms that decrease in size by 40% to 50% during gonadotropin-releasing hormone agonist treatment. During gonadotropin-releasing hormone agonist therapy most women are amenorrheic. After discontinuation of gonadotropin-releasing hormone agonist treatment, uterine and myoma size increase and a return to pretreatment menstrual patterns often occurs. Concerns about the safety of long-term hypoestrogenism have made long-term gonadotropin-releasing hormone agonist administration an undesirable treatment strategy. This article focuses on the use of gonadotropin-releasing hormone agonists as preoperative therapy in selected women undergoing hysterectomy or myomectomy and the combination of a gonadotropin-releasing hormone agonist with estrogen-progestin "add-back" treatment as a potential long-term medical therapy for women with symptomatic leiomyomas. Finally, an estrogen threshold hypothesis to assess the effects of circulating estrogen concentrations on different tissues, is presented. (Am J Obstet Gynecol 1990;163: 1114-9.)

Key words: GnRH agonist, uterine leiomyomas, hysterectomy, myomectomy, estrogen threshold hypothesis

The synthesis of the first gonadotropin-releasing hormone (GnRH) agonist in 1972[1] was followed by the development of a new class of drugs, the GnRH analogs, with potential widespread therapeutic applications in gynecology. Not since the development of oral contraceptives has there been so much excitement and enthusiasm among basic scientists, clinical investigators, and practitioners of reproductive medicine. It is anticipated that the GnRH agonists will have a major impact on gynecologic care in the 1990s.

Uterine leiomyomas are a common gynecologic problem that often present with symptoms related to enlarged uterine size, excessive bleeding, or both. Because

these neoplasms are estrogen dependent, it follows that a GnRH agonist–induced hypogonadal state will lead to a reduction or resolution of symptoms related to excessive myoma size or bleeding. In 1983 Filicori et al.[2] were the first to report that treatment of a woman with a myoma with the GnRH agonist [D-Trp^6]-GnRH for 3 months was able to induce a reduction in fibroid volume by 77% and cause cessation of hypermenorrhea, thus leading to an improvement in hemoglobin concentration from 7.4 to 12.8 gm/dl. Although other pharmacologic agents such as danazol or progestins may successfully induce amenorrhea, neither has been demonstrated to consistently cause uterine and leiomyoma shrinkage. Unfortunately, most women experience a relatively rapid reversal of these therapeutic effects after cessation of GnRH agonist treatment.[3, 4] The transient nature of these beneficial effects has limited the efficacy of GnRH agonists as a primary medical therapy for uterine leiomyomas. In addition, the profound hypoestrogenic environment induced by GnRH agonists has raised concerns regarding the safety of long-term GnRH agonist treatment. This article reviews clinical investigations in which GnRH agonists have been used to treat uterine leiomyomas and proposes potential uses of these agents in common clinical situations. It is hoped that well-designed, controlled clinical trials will continue to be performed to clarify and add to the potential therapeutic applications of GnRH agonists in women with large or symptomatic leiomyomas.

Clinical trials with GnRH agonists

The majority of symptoms associated with fibroids are related to myoma size, excessive bleeding, or both. Numerous studies have demonstrated that treatment of women with uterine leiomyomas with GnRH agonists for 3 to 6 months consistently results in a reduction of uterine volume. The reported range of uterine shrinkage is 34% to 61% (average, 40% to 50%).[3-9] The decrease in individual fibroid volume is less predictable, probably because of the heterogeneity of myoma composition.[10] Most studies suggest that a 12-weeks period of GnRH agonist treatment is needed to achieve near maximal reduction in uterine size. Unfortunately, regrowth of the uterus and fibroids may occur rapidly, with the uterus often approaching pretreatment size 3 to 4 months after cessation of therapy.[3, 4] Because the effects of GnRH agonists on uterine size are transient, this treatment may be viewed as temporary or as a possible adjunct to surgical therapy.

Treatment with GnRH agonists also induces amenorrhea in approximately two thirds of treated women; one third experience hypomenorrhea or spotting.[4] The induction of an amenorrheic state may be dose dependent; larger doses of GnRH agonist suppress menses more reliably.

The safety and side effect profile of GnRH agonist treatment appears to be related to the induced hypoestrogenic state. Most women experience vasomotor flushes, with insomnia, headaches, mood changes, and vaginal dryness occurring less frequently.[3, 4] One consistent concern among investigators is the potential for the long-term administration of a GnRH agonist to lead to rapid bone resorption, analogous to the situation immediately after the menopause. The data on bone resorption are confusing, primarily because of differences in techniques used to assess changes in bone density. With precision of bone density measurement techniques that vary from 1% to 5%, small changes in bone densities are difficult to document with certainty. Most studies evaluating bone density have reported no decrease or reversible decreases in women treated with GnRH agonists for up to 6 months[11-13]; some studies suggest that the decrease in bone density during GnRH agonist treatment is only partially reversible.[14] There is no reported study that has evaluated changes in bone density in women treated with GnRH agonists for longer than 6 months.

Because use of GnRH agonists decreases uterine and fibroid size and induces amenorrhea, one therapeutic strategy might include preoperative treatment in some women undergoing hysterectomy or myomectomy. The use of a GnRH agonist as a preoperative adjunct is reviewed below.

Preoperative GnRH agonist treatment

Hysterectomy, the only definitive cure for uterine leiomyomas, is often recommended in women with large or symptomatic fibroids who have completed childbearing or when myomectomy is considered difficult or hazardous. Many experts believe that risks and complications (i.e., nonautologous blood transfusion, urologic injury) associated with hysterectomy in women with leiomyomas are strongly correlated with preoperative uterine size and the presence or absence of anemia.[15]

There is one published study that evaluated the efficacy of the preoperative use of a GnRH agonist in women with leiomyomas before hysterectomy.[6] Lumsden et al. treated 13 women with fibroids with goserelin depot 3.6 mg every 28 days for 3 months before operation. Fourteen untreated matched controls with leiomyomas also underwent hysterectomy. The group of women treated with goserelin had a mean reduction in uterine volume of 40% (351 to 210 cm^3). Mean intraoperative blood loss was significantly less in the treated group compared with controls (235 vs 350 ml, $p < 0.01$). The decrease observed in intraoperative blood loss in women pretreated with GnRH agonist may be a result of (1) decreased uterine size that afforded the surgeon more operating space to isolate, secure, and divide vascular pedicles and (2) decreased uterine

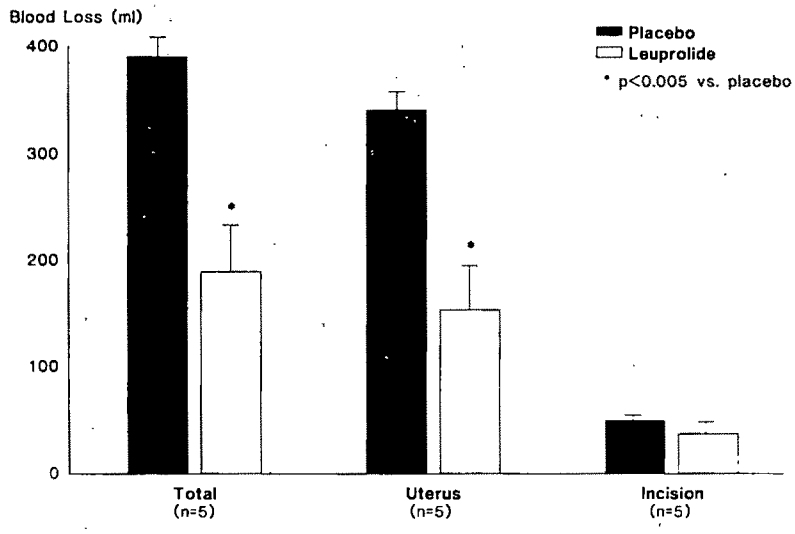

Fig. 1. Intraoperative blood loss at myomectomy for uteri with pretreatment volumes of ≥600 cm^3. Note: Total blood loss = uterine blood loss plus skin incision blood loss. (From Friedman AJ, Rein MS, Harrison-Atlas D, Garfield JM, Doubilet PM. A randomized, placebo-controlled, double-blind study evaluating leuprolide acetate depot treatment before myomectomy. Fertil Steril 1989;52:728. Reproduced with permission of the publisher, the American Fertility Society.)

artery blood flow, as demonstrated by Doppler studies,[16] suggesting that the uterus is less vascular after 2 to 4 months of GnRH agonist treatment.

In another study, 24 weeks of leuprolide acetate treatment in 7 women with uterine leiomyomas resulted in a significant increase in mean hemoglobin concentration from 12.7 to 14.1 gm/dl ($p < 0.01$).[7] Improvement in preoperative hematologic status may allow previously anemic women with hypermenorrhea the ability to donate blood for potential autologous blood transfusion. Because it is estimated that 30% of women with leiomyomas have menorrhagia or hypermenorrhea, GnRH agonist treatment may benefit a large number of women. The increase in preoperative hemoglobin concentration coupled with decreased intraoperative blood loss may decrease the need for nonautologous blood transfusion.

In addition to improving the patient's hematologic status, preoperative GnRH agonist treatment may offer other advantages. The decrease in uterine and myoma volume may "convert" an abdominal hysterectomy to one performed via a vaginal route. Vaginal hysterectomy has half the postoperative morbidity compared with abdominal hysterectomy.[17] In addition, fibroid shrinkage coupled with an atrophic endometrium may facilitate endoscopic resection of subserosal or submucous tumors. Finally, shrinkage of very large uteri may allow the surgeon to choose the stronger, more cosmetic Pfannenstiel skin incision instead of a midline vertical incision.

GnRH agonist treatment may also have a role in the preoperative management of women scheduled for myomectomy. Friedman et al.[9] reported that treatment with leuprolide acetate depot 3.75 mg every 4 weeks for 12 weeks before myomectomy resulted in less intraoperative blood loss in women with uterine leiomyomas at least 600 cm^3 in volume before treatment compared with placebo-treated controls. Mean intraoperative blood loss was 189 ml in five women with uteri > 600 cm^3 treated with leuprolide compared with 390 ml in five matched women treated with placebo ($p < 0.01$) (Fig. 1). When analysis was performed on all women (i.e., those with pretreatment volumes greater than and less than 600 cm^3) intraoperative blood loss was less in leuprolide-treated patients ($n = 9$) compared with controls ($n = 9$) (213 vs 302 ml) although this difference was not statistically significant. Not surprisingly, the difference in total intraoperative blood loss was attributed to differences in blood lost from uterine incisions and not from skin incisions. This study suggests that GnRH agonist treatment before myomectomy may help to decrease intraoperative blood loss in women with large uteri (i.e., >600 cm^3 or 16 gestational weeks). The potential advantages and disadvantages of preoperative GnRH agonist therapy are outlined in Table I.

GnRH agonist/hormone "add-back" studies

Several investigators have expressed concerns about primary GnRH agonist treatment in women with uterine leiomyomas including: (1) rapid regrowth of uterine-fibroid size after cessation of GnRH agonist therapy, (2) hypoestrogenic side effects, and (3) the potential for rapid or irreversible bone resorption in

women treated with GnRH agonists for more than 6 months. For these reasons several studies have evaluated the efficacy of GnRH agonist treatment combined with synthetic hormones. Administration of oral medroxyprogesterone acetate, 20 mg daily, has been shown to decrease the incidence of hot flushes in postmenopausal hypoestrogenic women.[18] In addition, this same dose of medroxyprogesterone acetate has been shown to decrease urinary calcium-creatinine and hydroxyproline/creatinine ratios in postmenopausal hypoestrogenic women.[19] Friedman et al.[7] evaluated the simultaneous combination treatment of leuprolide acetate, 0.5 mg subcutaneously, each day plus oral medroxyprogesterone acetate, 20 mg daily, in nine women with leiomyomas. Although eight of nine women treated reported no hot flushes, the mean decrease in uterine volume was only 14%. It is not certain why the addition of medroxyprogesterone acetate blocked the expected 40% to 50% decrease in uterine volume seen in women treated with leuprolide acetate alone.

In a small pilot study, five perimenopausal women aged 45 to 49 years with symptomatic leiomyomas were treated with daily leuprolide acetate 0.5 mg subcutaneously for 3 months, followed by leuprolide plus oral conjugated equine estrogens 0.625 mg days 1 through 25 each month and oral medroxyprogesterone acetate 10 mg days 16 through 25 each month for the ensuing 24 months.[20] The mean decrease in uterine volume was 49% at 3 months, with no further change in uterine volume over the next 2 years. All women had elimination of vasomotor flushes after conjugated equine estrogen-medroxyprogesterone acetate add-back; one woman required conjugated equine estrogen 1.25 mg on days 1 through 25. Bone density of the distal third of the radius (95% cortical bone, 5% trabecular bone) and ultradistal radius (25% cortical bone, 75% trabecular bone) demonstrated no changes over the 27-month treatment period as assessed by single-photon densitometry. Larger studies are needed to corroborate these findings before an add-back regimen can be recommended as a potential long-term medical treatment for fibroids.

The estrogen threshold hypothesis

This pilot study suggests that the concentration of estrogen required to reduce hot flashes and protect against bone loss may be less than the concentration of estradiol necessary to cause regrowth of myomas. This "estrogen threshold" hypothesis is shown schematically in Fig. 2. Three hypothetical estrogen zones are shown corresponding to different thresholds required for the growth or maintenance of various estrogen-dependent tissues. Zone A encompasses typical concentrations of estradiol seen throughout the menstrual cycle in premenopausal women. Estrogen concentrations in this range will support the growth or maintenance of estrogen-dependent tissues (i.e., myomas, bone). In zone C, estradiol levels are in the postmenopausal range, similar to estrogen concentrations after gonadal suppression with GnRH agonist treatment. Estrogen concentrations in this range cannot support tissue growth and, in fact, lead to regression of most estrogen-dependent tissues (i.e., myoma-myometrial shrinkage, bone resorption) and the presence of hypoestrogenic symptoms (i.e., hot flashes). In zone B estradiol levels are somewhat higher than castrate levels and are similar to those found in the early follicular phase. Estrogen concentrations in this range may be high enough to maintain the integrity of some estrogen-dependent tissues (i.e., bone) while causing regression in others (i.e., myomas). The goal of GnRH agonist hormone add-back therapy would be first to control the estrogen-dependent disease process by inducing a hypogonadal state with GnRH agonist treatment. Then, after hypoestrogenism has been achieved and the disease activity has been controlled, small amounts of estrogen, progestin, or both could be added back with the intent of reducing hot flashes and bone loss without causing reinitiation of myoma growth. With this strategy the clinician would attempt to maintain estrogen concentrations within zone B, the therapeutic window. The upper and lower estradiol concentrations in zone B would be expected to have considerable variation among individuals. Whereas some patients may have

Table I. Advantages and disadvantages of preoperative GnRH agonist treatment

Advantages gained by uterine-fibroid shrinkage
1. May allow vaginal hysterectomy
2. May decrease intraoperative blood loss
3. May allow Pfannenstiel incision
4. May facilitate endoscopic myomectomy
5. May decrease risk of ureteral injury
Advantages gained by induction of amenorrhea
1. May correct hypermenorrhea-menorrhagia–associated anemia
2. May improve ability to donate blood
3. May decrease need for nonautologous blood transfusion
4. May atrophy endometrium, facilitating hysteroscopic resection of submucosal tumors
Disadvantages
1. Delay to final tissue diagnosis
2. Degeneration of some leiomyomas necessitating piecemeal enucleation at myomectomy
3. Significant shrinkage of small intramural or submucosal tumors making them unrecognizable at myomectomy
4. Hypoestrogenic side effects (e.g., trabecular bone loss, vasomotor flushes, etc.)
5. Cost
6. Need to self-administer or receive injections in many cases
7. Vaginal hemorrhage in approximately 2% of patients

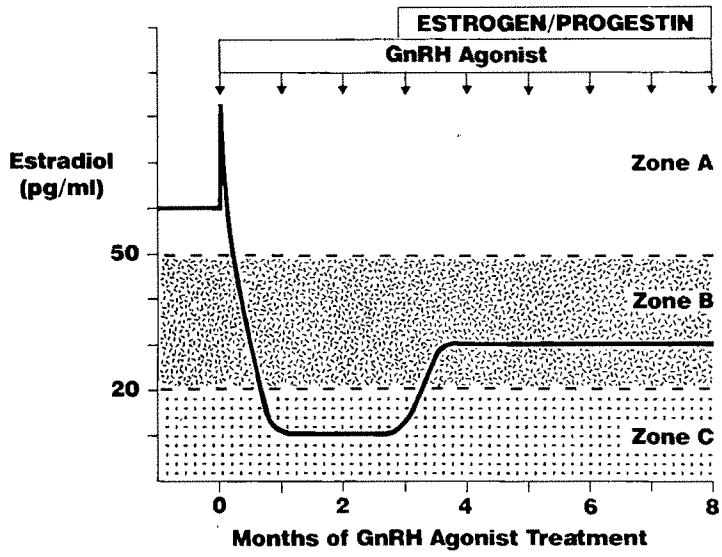

Fig. 2. Estrogen threshold hypothesis. *Zone A*, Typical circulating estradiol concentrations in premenopausal women are able to support myometrial-fibroid growth and prevent rapid bone resorption. *Zone B*, Therapeutic window. Myometrial and fibroid volume may decrease at these estradiol levels, but bone resorption is not accelerated. *Zone C*, Hypoestrogenism often attained during GnRH agonist therapy may lead to myometrial-fibroid shrinkage and rapid bone resorption. Note: Estradiol values for each zone may differ among patients.

Table II. Advantages and disadvantages of treating perimenopausal women with symptomatic leiomyomas with GnRH agonist

Advantages
1. Potential avoidance of operation
2. Reduction-resolution of symptoms
3. Possible correction of anemia in women with hypermenorrhea/menorrhagia
4. Possible facilitation of operation, if needed
Disadvantages
1. Delay-avoidance of tissue diagnosis
2. Inability to predict menopause necessitating several treatment courses, potentially increasing hypoestrogenism-related risks (i.e., osteoporosis)
3. Hypoestrogenic side effects
4. Cost
5. Need to self-administer or receive injections in many cases
6. Vaginal hemorrhage occurring in approximately 2% of patients

wide therapeutic windows making long-term medical management relatively easy to achieve, others may have narrow or absent therapeutic windows and would not be treated successfully by this GnRH-agonist hormone add-back approach.

Long-term GnRH agonist plus steroid add-back therapy will require extensive clinical investigation to clarify variables important to this therapeutic approach. For example, does the timing of estrogen and/or progestin add-back initiation affect treatment outcome? It is not known whether sequential therapy (i.e., GnRH agonist therapy for 3 to 6 months followed by GnRH agonist plus hormone add-back) is superior to simultaneous treatment (i.e., GnRH agonist and hormone add-back initiated simultaneously). The target estradiol concentration rate (i.e., the upper and lower limits of zone B) must be elucidated. Other variables that require further study include the optimum estrogen (i.e., estradiol, conjugated estrogens, estrone sulfate, ethinyl estradiol), and progestin (i.e., medroxyprogesterone acetate, norethindrone, norgestrel) formulations, the best route of administration (i.e., transdermal, oral, vaginal), length of therapy, need for calcium supplementation, and cost-effective monitoring of long-term treatment. Proper selection of patients is essential, and the physician must weight the potential benefits of long-term medical therapy against the potential risks of delaying or avoiding definitive tissue diagnosis.

Until further data are available we recommend that therapy for myomas be initiated with only GnRH agonist for 3 to 4 months and that initiation of steroid add-back be delayed until myoma-uterine volume has significantly decreased. As noted above, in one pilot study the simultaneous initiation of GnRH agonist therapy and progestin add-back resulted in no significant decrease in myoma volume.[7] By treating patients with a GnRH agonist alone for 3 to 4 months, the cells in the leiomyoma enter a quiescent state that may help to prevent a growth response to the steroid add-back.

If larger GnRH-agonist hormone add-back studies confirm the safety and efficacy of this treatment strat-

egy, it may be possible to treat perimenopausal women or other women with symptomatic leiomyomas who wish to delay or possibly avoid operation for longer than 6 months. The potential advantages and disadvantages of this treatment strategy are shown in Table II. GnRH-agonist hormone add-back regimens may also have applications in the long-term treatment of other sex-steroid-dependent disorders such as endometriosis, polycystic ovary syndrome, and premenstrual syndrome.

Treatment of women with uterine leiomyomas with GnRH agonists has been shown to result in a reduction in uterine and fibroid size, a decrease or abolition of menstrual flow with a resultant increase in hemoglobin concentrations, and a decrease in intraoperative blood loss in women undergoing hysterectomy or myomectomy. Long-term GnRH agonist treatment is limited by concerns about increased bone resorption and other hypoestrogenic side effects. Future research will focus on the safety and efficacy of long-term GnRH agonist hormone add-back regimens and preoperative treatment. In addition to the potential therapeutic uses of GnRH agonists in the treatment of uterine leiomyomas, these agents may be used as probes to help elucidate the biology of these common symptom-producing tumors.

We thank Ms. Carolyn Edwards for her expert preparation of this manuscript.

Contraception and ectopic pregnancy risk

Adele L. Franks, MD,[a] Valerie Beral, MB, BS,[b] Willard Cates, Jr., MD, MPH,[b] and Carol J. R. Hogue, PhD[a]

Atlanta, Georgia

Studies of the association of ectopic pregnancy with contraception have generated a conflicting array of results because of methodologic differences between studies. We estimated the absolute incidence rates of ectopic pregnancy for various contraceptives by multiplying the pregnancy rate by the proportion of pregnancies with ectopic implantation for each method. Our results indicated a more than 500-fold difference in ectopic pregnancy incidence, from a low of 0.005 ectopic pregnancies per 1000 woman years of oral contraception or vasectomy to a high of 2.6 per 1000 woman years of no contraception. These estimated incidence rates should be useful for clinicians and patients seeking to better understand the risks and benefits of contraceptives. (Am J Obstet Gynecol 1990;163:1120-3.)

Key words: Pregnancy, ectopic; contraception; intrauterine contraceptive device; family planning

The incidence of ectopic pregnancy has increased dramatically over the last 20 years.[1-3] Possible explanations include the increased prevalence of pelvic inflammatory disease and sexually transmitted diseases, increased clinical suspicion and improved early diagnostic techniques for ectopic pregnancy (quantitative serum pregnancy hormone tests, ultrasonography, laparoscopy), the trend toward delaying childbearing until older ages when ectopic pregnancy becomes a greater risk, and the role of contraceptive practice.[1, 3-8] Studies of the association of ectopic pregnancy with contraceptive methods, in particular, the intrauterine contraceptive device (IUD),[3, 5, 6] have generated a conflicting array of results that may be a source of confusion for clinicians desiring to provide the best contraceptive alternatives to their patients.

Most studies of the possible association of contraception and ectopic pregnancy have used the case-control study design because it is the most feasible method for studying rare diseases.[9] Such a study design compares persons who have the disease in question (cases) with persons free of the disease (controls). Crucial to interpreting the results are that the controls be chosen from the same population of persons as the cases and that the controls have the potential for being exposed to the same risk factors as the case group. Selecting a control group for a case-control study of ectopic pregnancy is not a simple matter[10, 11]; some researchers have selected obstetric patients, and others nonpregnant women, as controls,[3] leading to substantially different results.[3, 5, 6, 11]

For example, in a study about the use of the IUD, the selection of the control group may determine whether the IUD appears to protect against ectopic pregnancy or to increase the risk of ectopic pregnancy; relative risk estimates range from 0.5 to 32, depending on study design.[3] To illustrate, if obstetric patients with intrauterine pregnancies are selected as controls, a low percentage of these women will have conceived while using the IUD because the IUD largely prevents intrauterine implantation. In addition, the spontaneous abortion rate is elevated among intrauterine pregnancies that result from IUD failure, and the likelihood of an induced abortion among IUD users who do not spontaneously abort also may be high. Thus women with second- or third-trimester intratuerine pregnancies are less likely than the general population to have been using an IUD. Comparing these women with those who have an ectopic pregnancy may therefore yield an elevated risk associated with IUD use among women in the case group, even if their prevalence of IUD use is not particularly high. In contrast, if nonpregnant

Table I. Estimated incidence rates of ectopic pregnancy by contraceptive method

Contraceptive method	*Lowest expected pregnancy rate per 1000 woman years** (A)	*Proportion ectopic implantation** (B)	*Estimated ectopic pregnancy incidence rate per 1000 woman years* (A × B)
Oral contraceptive†	1	0.005	0.005
Vasectomy	1	0.005	0.005
Condom	20	0.005	0.100
Diaphragm	30	0.005	0.150
Tubal sterilization	2	0.159	0.318
IUD‡	20	0.051	1.020
None	520	0.005	2.600

*See material and methods section for origin of these numbers.
†Combination estrogen-progestin only.
‡Unmedicated only.

women are selected as controls, the opposite conclusion is likely. Nonpregnant, sexually active women are more likely to be using contraception, and thus they may have a higher prevalence of IUD use than women in the case group, leading one to conclude that IUD use is protective against ectopic pregnancy. Interpretation of these results must be limited in scope to the comparisons actually studied. Thus no general statement may be made about whether IUD users are at increased or decreased risk of ectopic pregnancy.

For an individual clinician or patient to use the information from case-control studies in selecting a contraceptive method would be, at best, a challenging endeavor. Instead, knowing the actual rates of ectopic pregnancy among cohorts of women using various contraceptive methods might prove more useful. Unfortunately, such information can be acquired only by follow-up of large numbers of women over time (cohort study design), a process that is expensive and time-consuming. Such studies are therefore rare. Two cohort studies conducted in the 1960s and early 1970s in the United States and the United Kingdom provide sufficient information on ectopic pregnancy rates among IUD users.[12, 13] Little information exists on ectopic pregnancy rates associated with other contraceptive methods.

In this article we estimate the incidence rates of ectopic pregnancy per 1000 woman years of using various contraceptive methods to clarify the magnitude of ectopic pregnancy risk and to determine the relative ranking of risk for each contraceptive method.

Material and methods

To calculate estimated rates of ectopic pregnancy per 1000 woman years of use for each contraceptive method, we assumed that the ectopic pregnancy rate was the product of two factors: (1) the incidence rate of pregnancy (i.e., the conception rate) per 1000 woman years and (2) the proportion of pregnancies implanting in an ectopic location (outside the uterine fundus).

For women using contraception the pregnancy rate per 1000 woman years was taken as the "lowest expected" ("method") failure rate associated with the use of each contraceptive method per 1000 women in the first year of use.[14] This rate is based on the assumption of consistent and correct use of the method for the entire year. For women not using contraception, the pregnancy rate per 1000 woman years was taken as the average annual pregnancy rate per 1000 women not using contraception.[15]

For IUD users we derived the proportion of pregnancies that implant in an ectopic location from the two large cohort studies (mentioned earlier) in which, at the time of publication, more than 98% of the women enrolled used nonmedicated devices.[12, 13] The proportion of pregnancies that were ectopic among the women using IUDs (0.043 in the U.S. study and 0.072 in the U.K. study) were averaged (directly weighted by the number of woman years of IUD use in each study), yielding 0.051 for our calculations.

For women who used combination oral contraceptives, who used barrier methods, and who were partners of vasectomized men, we assumed that the contraceptive method did not affect the site of implantation; therefore we assumed that the proportion of pregnancies implanting in an ectopic location was 0.005, approximately equal to the overall proportion among reported pregnancies in the U.S. population during the early 1970s.[16] For women with tubal sterilization failures we obtained the proportion with ectopic implantation from literature reviews.[7, 8]

The IUD was the only contraceptive method for which actual observed rates of ectopic pregnancy per 1000 woman years of use were available from large cohort studies.[12, 13] These empiric rates were averaged (directly weighted by number of woman years of use in each study) and were compared with those calculated as described above.

Results

The resulting estimated ectopic pregnancy rates by contraceptive method vary more than 500-fold from the lowest rate of 0.005 per 1000 woman years among

women who used combination oral contraceptives or who were partners of vasectomized men, to the highest rate of 2.6 per 1000 woman years among women using no contraception (Table I). Thus, although using an IUD carries a higher rate of ectopic pregnancy than using barrier methods, sterilization, or oral contraception, failure to use any contraception has the highest estimated rate of ectopic pregnancy.

For IUD use, the calculated ectopic pregnancy rate can be compared with the actual rates of 1.0 per 1000 woman years in the U.S. study and 1.2 per 1000 woman years in the U.K. study referred to previously.[12, 13] On the basis of these numbers, the weighted average of 1.06 per 1000 woman years compares favorably with the calculated rate of 1.02 per 1000 woman years derived by multiplying the pregnancy rate and the proportion of resulting pregnancies that were ectopic (Table I).

Comment

We believe that expressing risk of disease, whenever possible, in terms of absolute rates of occurrence, rather than only in relative terms, is more useful for clinical decision making. For ectopic pregnancy we believe relative risk estimates from case-control studies are especially confusing because the choice of control group profoundly affects interpretation of results.

To estimate rates of occurrence of ectopic pregnancy in the absence of sufficient cohort data, we assumed that the proportion of pregnancies implanting in an ectopic location did not differ among women who used combination oral contraceptives, women who used barrier methods, women who were partners of vasectomized men, and women who used no contraception. If this assumption is incorrect, our resulting estimates of incidence rates for ectopic pregnancy might be incorrect as well; however, on the basis of current knowledge, we know of no reason to question this assumption. For those who prefer to make different assumptions regarding the likelihood of ectopic implantation, our methods may be easily applied, by substituting different numbers.

Similarly, although we used the "lowest expected" ("method") failure rates for the various contraceptive groups for our calculations, one could easily use the "typical" ("user") failure rates among women using contraception instead. While the former is based on the assumption of consistent and correct use of the contraceptive method, the latter is based on "typical" couples, including those who do not use the contraceptive method consistently or correctly. To calculate ectopic pregnancy rates based on "typical" failure rates, one could substitute pregnancy rates of 30 per 1000 women for oral contraceptives, 1.5 per 1000 women for vasectomy, 120 per 1000 women for condoms, 180 per 1000 women for the diaphragm, 4 per 1000 women for tubal sterilization, and 60 per 1000 women for the IUD.[14] This substitution results in estimated "typical" ectopic pregnancy rates of 0.15, 0.0075, 0.60, 0.90, 0.64, and 3.06 per 1000 woman years of use, respectively.

It should be noted that we used the first-year failure rates for women who used the various contraceptives while we used the average annual pregnancy rate for women who used no contraception. Because failure rates tend to decline over time for reversible contraceptives, our results may be biased in the direction of exaggerating the ectopic pregnancy risk among women using contraception. For women using sterilization to avoid pregnancy, failure rates over time may depend on method of occlusion and other factors that are not yet fully understood. Therefore predicting the direction of any potential bias in our calculations regarding sterilization is difficult.

We also assumed the ectopic pregnancy rate to be the product of the pregnancy rate and the likelihood of ectopic implantation. Again, no data exist to challenge this assumption, and our own estimate of the ectopic prengancy rate among IUD users on the basis of this multiplicative assumption compares favorably with the actual rates reported in two large cohort studies.

The only available cohort data reflect rates of ectopic pregnancy among IUD users during the 1960s and early 1970s. To make meaningful comparisons, we estimated the occurrence of ectopic pregnancy for other methods on the basis of data as close in time as possible to the IUD cohort studies. Note, however, that the currently used copper-containing IUDs have lower failure rates than the nonmedicated IUDs,[14] which were predominantly used in the 1960s and early 1970s. Thus the ectopic pregnancy rate associated with IUD use may be somewhat reduced in recent years. On the other hand, recent information suggests that the proportion of ectopic pregnancies among pregnancies resulting from tubal sterilization failure may vary according to method of occlusion and may be higher than previously believed, especially for pregnancies occurring after tubal sterilization by electrocoagulation.[17] Further research is necessary to clarify this issue.

Though our estimates are imprecise, and changes in risk over time may have occurred, the differences in magnitude of ectopic pregnancy risk between contraceptives are so large that we believe the relative ranking of risk to be correct. We hope that expressing the risk of ectopic pregnancy associated with contraceptive methods as rates of occurrence rather than as relative risks will be meaningful in the clinical setting. In particular, the fact that ectopic pregnancy risk appears to differ little between women who use IUDs and women who use no contraception should be reassuring for

those women for whom the IUD is otherwise the best contraceptive option.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Calcium supplementation during pregnancy may reduce preterm delivery in high-risk populations

Jose Villar, MD,[a] and John T. Repke, MD[b]
Bethesda and Baltimore, Maryland

Results are presented of a randomized, double-blinded controlled clinical trial of calcium supplementation (2.0 gm of elemental calcium as calcium carbonate) and a placebo. All participants were 17 years of age or less and clinically healthy. Patients were enrolled by the twenty third week of gestation. The mean duration of calcium supplementation or placebo was approximately 14 weeks. Treatment consisted of 2.8 (±1.5) tablets per day in the placebo group ($N = 95$) and 3.0 (±1.4) tablets per day in the calcium group ($N = 94$). Dietary calcium intake was similar in both groups at about 1200 mg/day. The calcium group had a lower incidence of preterm delivery (<37 weeks; 7.4% vs 21.1%; $p = 0.007$); spontaneous labor and preterm delivery (6.4% vs 17.9%; $p = 0.01$); and low birth weight (9.6% vs 21.1%; $p = 0.03$). This effect was also present after stratified analysis by level of treatment compliance, urinary tract infection, and chlamydial infection. Life-table analysis demonstrated an overall shift to a higher gestational age in the calcium group compared with the placebo group (log-rank test, $p = 0.02$). As suggested previously, the observed effect could be mediated by a reduction in uterine smooth muscle contractibility. If confirmed by future research, these results could represent an important preventive intervention for prematurity in high-risk populations. (AM J OBSTET GYNECOL 1990;163:1124-31.)

Key words: Calcium supplementation prematurity, high-risk population

Prematurity and low birth weight are among the leading causes of perinatal and infant mortality in both developing and developed populations.[1, 2] Therefore their prevention, even if achieved at modest proportions, would have major health implications.

We previously reported blood pressure reduction among pregnant and nonpregnant women who received calcium supplementation, observations that are supported by similar evidence from hypertensive subjects.[6] Two recently published literature reviews summarized these findings.[6, 7]

It has been postulated that the blood pressure–lowering effect of calcium supplementation involves mechanisms related to parathyroid hormone levels, negative calcium balance, and plasma renin activity.[6, 8] These proposed mechanisms would ultimately influence intracellular free (cytosolic) calcium concentrations in smooth muscle cells, [6] thus reducing smooth muscle cell tone and increasing its relaxation. Therefore high calcium intake would reduce blood pressure by reducing smooth muscle reactivity. If this is the case, a similar effect should be present at the level of the uterine muscle, particularly in the third trimester of pregnancy when the uterus represents the largest mass of smooth muscle in mammals. Interestingly, there are data to support an association between pregnancy-induced hypertension, preeclampsia, and increased uterine contractibility.[9, 10]

We previously hypothesized that calcium supplementation during pregnancy can reduce smooth muscle contractibility and tone[6] and that this effect can be clinically manifested by a reduction in blood pressure and a reduction in the incidence of premature labor and delivery.

This article presents the results of a randomized, double-blinded placebo-controlled clinical trial of the effect of calcium supplementation during pregnancy (2.0 gm/day) on the incidence of prematurity and preterm labor. The a priori hypothesis that calcium supplementation reduces the incidence of prematurity (<37 weeks) is tested.

Material and methods

This randomized clinical trial was conducted at the Adolescent Pregnancy Clinic of The Johns Hopkins Hospital in Baltimore between 1985 and 1988. All pa-

tients were 17 years of age or younger at the time of recruitment. Most of the subjects were nulliparous [84 in the calcium group, 78 placebo group (NS)] with a known last menstrual period and singleton pregnancies. All were free of any underlying medical disorders, determined by history, physical examination, and laboratory tests.

Patients were contacted during the first prenatal visit about participation in the project. By the twentieth week of gestation enrollment to the study was offered and parental consent or patient informed consent was obtained. If patients agreed to participate they were randomized to the calcium and placebo group at the next prenatal visit. A computer-generated list of random numbers was used to allocate the corresponding treatments. Opaque envelopes with the bottles numbered were located at the clinic and the project coordinator was in charge of the administration of the treatment assigned. Prenatal care was carried out according to the protocols of The Johns Hopkins Adolescent Pregnancy Program, and under the direct supervision of its medical director (J. T. R). The study protocol was approved by The John Hopkins Hospital's Joint Committee on Clinical Investigation. Patients received a small monetary compensation for travel and compliance with the study protocol.

The calcium supplementation group received four tablets of calcium carbonate (OSCAL 500, Marion Laboratories, Kansas City, Mo.) per day. Each tablet provides 500 mg of elemental calcium for a total of 2.0 gm/day. This dosage was based on our previous evidence on the effect of calcium supplementation on blood pressure during pregnancy.[4,8] The placebo group received four tablets of the same weight, size, color, and organoleptic characteristics as the calcium tablets. All of the tablet containers were prepared at The Johns Hopkins Hospital Pharmacy. Patients were prescribed prenatal vitamins containing 200 mg of calcium and 100 mg of magnesium per day.

Total intake, including a detailed description of calcium-containing food stuffs, was evaluated three times during pregnancy by a senior nutritionist by means of food patterns and 24-hour recall methods. These data were further analyzed with regard to specific nutrient content.

Treatment compliance was assessed at each visit by the project coordinator. Patients were questioned during each visit about the number of tablets taken and the project coordinator counted the number of tablets left in the container as many times as possible during pregnancy. The number of tablets taken of the total number of tablets required to be taken between prenatal visits (compliance rate) was calculated for the calcium and placebo groups. With that information and the time elapsed between visits, the actual number of tablets reported taken per day was calculated for three periods during pregnancy for the two treatment groups.

Gestational age was calculated using the best obstetric estimation by the attending obstetrician who was totally unaware of the treatment groups. This evaluation was done at the time of randomization and was corroborated during pregnancy. It includes last menstrual period information (consideration menstrual patterns and contraceptive use), several standard ultrasonographic measurements between 16 and 20 weeks, or at the time of the first visit, fundal height. If the gestational age based on the last menstrual period and the ultrasonographic estimation differed more than 2 weeks, the ultrasonogram was used for gestational age calculation; otherwise gestational age was based on the last menstrual period.

The incidence of the following events was calculated for the analysis: *preterm labor without delivery*, diagnosed by obstetricians unaware of the treatment group and based on uterine activity of at least four contractions in 20 minutes or eight contractions in 1 hour after the patient was admitted to the hospital and discharged after 24 hours without delivery; *preterm labor and delivery* during the same hospital admission; *preterm delivery* (<37 weeks); *delivery between 30 and 37 weeks; idiopathic prematurity*, including only preterm (<37 weeks) deliveries without previous medical or obstetric complications; *spontaneous prematurity*, including only preterm deliveries with spontaneous onset of labor regardless of vaginal or cesarean section delivery.

The hypothesis tested was whether provision of calcium supplementation (2 gm/day) to high-risk pregnant adolescents reduces uterine muscle tone and contractions, resulting in a lower rate of prematurity. A sample size of 95 subjects in each group has a statistical power of 80% to detect a reduction in prematurity (<37 weeks) rates from 20% to 7% at an α-level of 0.05. The expected 20% incidence of prematurity in the placebo group is obtained from values previously reported from The Johns Hopkins adolescent population.[11] All subjects were included in the treatment group to which they were originally randomized regardless of any follow-up and treatment compliance experiences.

The incidence of preterm delivery and all other secondary outcomes were compared between treatment groups using Mantel-Haenszel χ^2, Fisher's exact test, or t test, when required. To evaluate the treatment effect on the complete gestational age distribution, a life-table analysis was performed with calcium and placebo treatments as the independent variable and the delivery at different gestational ages as the outcome variable. The life-table analysis was performed for all patients, including dropouts up until the time they left the study. Life tables were compared with the log-rank test. Two-tailed p values are presented.

Table I. Population characteristics by treatment group

	Calcium (N = 95)	*Placebo (N = 95)*	*p Value*
Maternal age (yr) (mean ± SD)	16.2 ± 0.8	16.3 ± 0.9	NS
Education (yr) (mean ± SD)	9.3 ± 1.3	9.4 ± 1.5	NS
No. of prenatal visits (mean ± SD)	10.2 ± 3.7	10.0 ± 4.2	NS
Maternal height (in) (mean ± SD)	64.6 ± 10.9	65.8 ± 14.9	NS
Black race	92.6	94.7	NS
Marital status single (%)	97.9	98.9	NS
Previous preterm delivery (<37 wk) (%)	2.1	2.1	NS
Previous low birth weight (≤2500 gm) (%)	2.1	2.1	NS
Previous pregnancy-induced hypertension (%)	2.1	2.1	NS
Spontaneous abortions (%)	5.3	8.4	
Induced abortions (%)	15.2	18.9	NS
Primigravid (%)	70.5	61.0	NS
Nulliparous (%)	88.4	82.1	NS

Calcium supplementation of 2.0 gm/day of elemental calcium.

Table II. Population characteristics at the time of randomization

	Calcium (N = 95)	*Placebo (N = 95)*	
Gestational age (wk)	23.7 ± 4.3	23.4 ± 3.8	NS
Uterine height (cm)	23.7 ± 4.1	23.6 ± 3.8	NS
Maternal weight (kg)	63.0 ± 10.6	67.4 ± 13.5	$p < 0.01$
Systolic blood pressure (mm Hg)	103.1 ± 9.2	102.4 ± 10.4	NS
Diastolic blood pressure (mm Hg)	60.9 ± 8.8	61.3 ± 8.0	NS

Values are mean ± SD. Calcium supplementation of 2.0 gm/day of elemental calcium.

Results

Table I presents the baseline population characteristics for the 190 study patients. No statistically significant differences were observed for all variables. Table II presents patient characteristics at the time of randomization. No differences between groups were detected with the exception of maternal weight. The calcium group had lower mean maternal weight (63.0 ± 10.6 kg) than the placebo group (67.4 ± 13.5 kg; $p < 0.01$).

There was a tendency to a higher incidence of bacteriuria (11.7% vs 5.4%; NS) and symptomatic chlamydia vaginitis (7.4% vs 3.2%, NS) in the placebo group compared with the calcium group. No differences were observed in the incidence of either pyelonephritis (1.1% for calcium group vs 2.1% for placebo group, NS), or sexually transmitted diseases (14.7% for calcium vs 15.8% for placebo group NS).

Table III shows data on the treatment compliance for the two study groups. Both groups started treatment at similar gestational age and continued under treatment for similar length of time (14.1 ± 4.4 weeks for calcium group vs. 13.2 ± 4.9 weeks for placebo group, NS). The actual number of tablets reported taken was also similar in both groups at different points in gestation and for the total follow-up period; overall, patients took a daily average of three tablets per day (75% of the expected number of tablets).

Selected nutrient intakes at baseline, during the third trimester of pregnancy, and for the overall study period (average of all intakes recorded per patient) by treatment group are presented in Table IV. No differences were observed between groups for the nutrients evaluated. Mean calcium intake for both groups was approximately 1200 mg/day throughout pregnancy.

The calcium supplementation group had a lower incidence of preterm labor and delivery (7.4% vs 16.8%; $p < 0.05$), preterm labor without delivery (3.2% vs 7.4%; NS), preterm delivery <37 weeks, (7.4% vs 21.1%; $p = 0.007$), preterm delivery ≥30 but <37 weeks (4.4% vs 15.7%; $p < 0.01$), low birth weight (≤2500 gm, 9.6% vs 21.1%; $p = 0.03$), and preterm

Table III. Treatment compliance by supplementation groups

	Calcium (N = 91)	*Placebo (N = 92)*	*p Value*
Period under treatment 1 week	14.1 ± 4.4	13.2 ± 4.9	NS
Actual no. of tablets taken per day			
Total period	3.0 ± 1.4	2.8 ± 1.5	NS
<30 wk	3.1 ± 1.4	2.8 ± 1.3	NS
30-34 wk	2.7 ± 1.5	2.9 ± 1.4	NS
>34 wk	3.1 ± 1.5	2.8 ± 1.6	NS

Values are mean ± SD. Ideal number of tablets per day = 4 (500 mg of elemental calcium each tablet). Three patients in the placebo group and four in the calcium group abandoned treatment at different times during the study and complete compliance information could not be obtained.

Table IV. Estimated daily nutrient intakes by treatment group

	Baseline	*Third trimester*	*Overall**

delivery after spontaneous labor (6.4% vs 17.9%; $p = 0.01$). No effect was observed on the incidence of intrauterine growth retardation and premature rupture of membranes (<37 weeks, >24 hours before initiation of labor; Table V).

All seven preterm deliveries in the calcium group were associated with medical complications ($n = 3$), vaginal infections ($n = 6$), sexually transmitted diseases ($n = 2$), premature rupture of membranes ($n = 2$), proteinuria ($n = 1$), and pregnancy-induced hypertension ($n = 1$). Fourteen of the preterm deliveries in the placebo group associated were also associated with these complications. Therefore the incidence of idiopathic prematurity is 0 of 94 patients in the calcium group and 6.3% in the placebo group ($p = 0.01$; Table V).

The mean duration of labor was longer in the calcium group (12.0 ± 7.4 hours than in the placebo group (9.9 ± 6.2 hours; $p = 0.05$). Gestational age at birth was 1.3 weeks longer ($p = 0.01$) and infants were 189 gm ($p = 0.06$) heavier in the calcium group than in the placebo group (Table VI).

The incidence of pregnancy-induced hypertension was 1.7 times higher in the placebo group than in the calcium group (NS), and the incidence of preeclampsia was 3.4% in the placebo group with no cases observed in the calcium group ($p = 0.10$; Table VI).

When only those patients with vaginal deliveries are included in the analysis the incidence of preterm delivery (<37 weeks) was 6.5% for the calcium group ($n = 77$) and 16.2% for the placebo group ($n = 74$; $p = 0.05$); the values for low birth weight (≤2500 gm) in this subgroup were 11.2% and 20.5% ($p = 0.08$) for the calcium and placebo groups, respectively.

Although the differences in the proportion of bacteriuria and chlamydia vaginitis between groups were not statistically significant, it was thought that the observed tendency could influence the results. A stratified

Table V. Pregnancy outcome by treatment group

analysis was therefore performed by infection status. Among the noninfected patients, the incidence of prematurity was 8.1% in the calcium group ($n = 86$) and 24.7% in the placebo group ($n = 77$; $p = 0.003$). The small number of patients in the infected groups precludes any further consideration of the calcium effect among them.

The effect of calcium supplementation on the incidence of prematurity was further studied by level of treatment compliance. Three patients in the placebo group and four in the calcium group did not have complete compliance information and are not included in this analysis. In the high-compliance calcium supplementation group (>50% of ideal treatment; $n = 49$), no cases of prematurity were observed, whereas the preterm rate was 9.5% in the high-compliance placebo group ($n = 42$; $p = 0.04$). The incidence of prematurity was also lower in the low-compliance calcium group (<50% of ideal treatment; $n = 41$; 17.1%) compared with the low-compliance placebo group ($n = 50$; 26.0%; NS). These data suggest an independent effect on prematurity of both calcium supplementation and treatment compliance.

Fig. 1 presents the cumulative probability of delivery (8 percent) for two treatment groups at different periods of gestation. All participants (including one drop-out until the time she left the study) are included. Information is derived from life-table analysis using the Kaplan-Meier method Statistical Analysis Systems test procedure; differences between the two life tables have

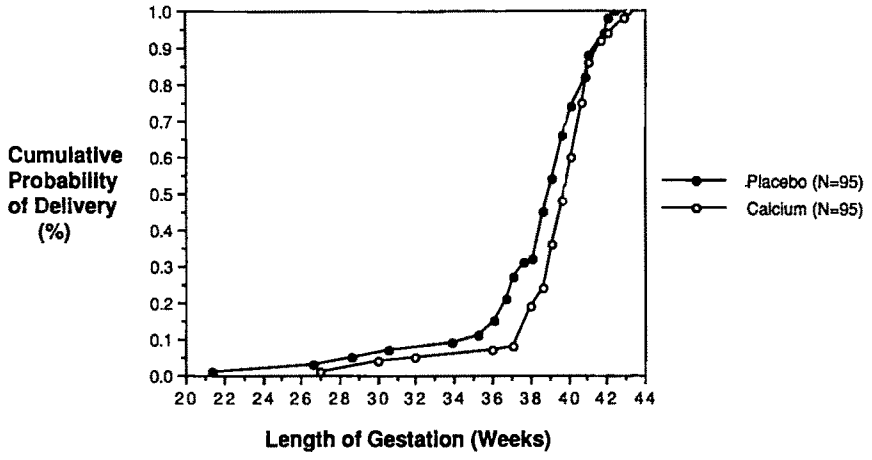

Fig. 1. Calcium supplementation and prematurity. Cumulative probability of delivery (percent) from life-table analysis for each treatment group. At all gestational ages the calcium group has lower risk of delivery than the placebo group (log-rank test, $p = 0.02$)

been statistically tested with the log-rank and Wilcoxon tests. The calcium group had lower risk of delivery at all gestational ages than the placebo group ($p = 0.02$) (Fig. 1). Finally, urinary and chlamydial infections as well as prepregnancy weight, the identified possible confounding variables, were not associated with prematurity when included in the life-table analysis ($p = 0.10$).

Comment

We have presented evidence from a double-blind, randomized placebo-controlled clinical trial of the effect of calcium supplementation on the incidence of preterm delivery. Groups were similar in several baseline characteristics known to be related to preterm delivery.

The calcium group had lower maternal weight at the time of randomization; however, if an effect was present, it would be in the direction of increasing prematurity or low birth weight in this group. Exclusion of patients with urinary or vaginal infections or inclusion of these variables in the life-table analysis demonstrated that the observed differences in prematurity rates between treatment groups could not be explained by these baseline differences.

Nutrient intakes were similar in both groups and the mean calcium intake was approximately 75% of the recommended level for pregnant adolescents at the time the study was conducted.[12]

As expected among these high-risk adolescents, treatment compliance showed large variability. However, the calcium effect was observed at both compliance levels with the strongest effect among those patients with higher compliance rates. Interestingly, treatment compliance, a proxy indicator for adherence to medical care in general, education, or personal motivation also had an independent effect preventing preterm delivery.

Finally, patients in the calcium group, in agreement with previous reports,[4, 13] had a lower incidence of preeclampsia and pregnancy-induced hypertension without reaching statistically significant levels because of small sample size. Although it is possible that part of the prematurity effect could be mediated through this mechanism, it is unlikely to explain an effect of this magnitude. We expect to evaluaute this association in more detail in a larger, multicenter clinical trial.

Therefore, we believe that the observed results on preterm delivery are unbiased and are likely to represent a true biologic effect. More data are needed to confirm this evidence. If the results are valid, obstetricians could incorporate this relatively easy and inexpensive preventive action into the prenatal care of high-risk poplations.

A recent report[13] provided additional information on the effect of 2 gm of elemental calcium supplementation during pregnancy. This study confirmed the previously reported blood pressure effect.[4] The percentage of deliveries between 36 and 38 weeks was 10.9% for the calcium group and 15.7% for the placebo group. Similar to our study, the calcium group had a higher mean birth weight (265 gm difference) and a statistically significant longer gestational age (39.3 weeks in the calcium group and 38.7 weeks in the placebo group; ($p < 0.05$).[13] Therefore, these data would seem to support the results presented in this article.

Currently, we do not have definitive physiologic explanations of the mechanisms involved in these observed effects. The role of ionized calcium in smooth muscle contraction, in uterine muscles,[14, 15] and vascular tissues[16, 17] has been extensively studied, including alterations in calcium concentration associated with hy-

pertension.[18] We[3] and others[4, 7] have demonstrated blood pressure reduction with calcium supplementation, and this effect is suggested to be mediated by induced changes at the vascular smooth muscle level.[6]

Therefore, it is logical to expect that a similar action will be observed at the uterine level, particularly near term when the uterus represents the largest mass of smooth muscle in mammals. We do not think that high calcium intake is responsible for affecting uterine contractibility by a direct effect on uterine extracellular ionized calcium. It is more likely that high calcium intake is related to an effect on membrane calcium channels, particularly those controlled by hormones.[15]

For instance, high calcium intake, as we recently have proposed,[6, 8] could participate in these mechanisms by reducing the level of parathyroid hormone, thus lowering intracellular free calcium levels and increasing smooth muscle relaxation. The parathyroid hormone effect on intracellular concentration of calcium has been demonstrated in several types of cells.[6, 19-2] Two mechanisms can mediate this action: an increase in cellular membrane permeability to calcium and an activation of adenyl cyclase and an increase of cyclic adenosine monophosphate with a consequent liberation of calcium from the mitochondria to the cytosol.[6]

Seemingly paradoxically, calcium channel blockers are also known to reduce blood pressure and uterine contractibility[22] and have been suggested for the treatment of preterm labor[23] and preterm labor in hypertensive patients.[24] It has been recently shown that diltiazem, a calcium channel blocker, lowers serum parathyroid hormone in vivo and in vitro in a dose-dependent fashion.[25] This observation suggests that lowering the level of pregnancy-induced hypertension could be the mechanism explaining the similar effects of high calcium intake and calcium channel blockade on smooth muscle contractibility.

Finally, recent evidence from our unit also suggests that the effect may be mediated through or by changes in the renin-angiotensin system and its interaction with pregnancy-induced hypertension.[8] In vitro studies appear to support these relationships.[26]

Clearly, the mechanisms involved in the calcium supplementation effect on smooth muscle contraction and on the incidence of prematurity require extensive physiologic research. We think, however, that on the basis of data presented in this article that the feasibility of implementing this relatively simple intervention in high-risk populations and the magnitude of the expected impact on prematurity are strong arguments in favor of further extensive clinical evaluation of this promising preventive prenatal care activity.

Linda Markush, MPH, was the project coordinator during the study period. Dr. J. M. Belizan was the consultant for the project.

The association of intrapartum asphyxia in the mature fetus with newborn behavior

James A. Low, MD, Darwin W. Muir, PhD, Elizabeth A. Pater, RN, and E. Jane Karchmar, BA
Kingston, Ontario, Canada

A matched cohort study of mature newborns with biochemically determined intrapartum fetal asphyxia and mature newborns with normal blood gas and acid-base assessments at delivery were studied to demonstrate the effect of fetal asphyxia on newborn behavior as expressed by the Brazelton newborn behavioral assessment scale. The newborn behavioral assessment scale was administered 3 days after delivery and again 2 weeks after delivery. The Lester newborn behavioral assessment scale summary scores for the group with asphyxia were of the same order as those in the control group. This was also true of the group of newborns with asphyxia with the more severe metabolic acidosis and those with low Apgar scores. These findings support the contention that many newborns who have undergone an intrapartum asphyxial insult will not have evidence of central nervous system injury and that the threshold of central nervous system injury is at the severe end of the spectrum of asphyxia as expressed by a metabolic acidosis. (AM J OBSTET GYNECOL 1990;163:1131-5.)

Key words: Fetal asphyxia, newborn behavior

Laboratory and clinical evidence suggest that fetal asphyxia can cause central nervous system injury and in surviving newborn infants result in motor and cognitive deficits.[1] Freeman[2] summarized the National Institutes of Health consensus conference on prenatal and perinatal factors associated with brain disorders by stating: "There appear to be degrees and durations of hypoxia tolerated without obvious effects on mental and motor function, yet, when the duration and severity of hypoxia exceed these thresholds motor dysfunction results and may be accompanied by mental retardation."

Although there are thresholds of asphyxia beyond which damage becomes manifest, these thresholds remain to be defined. A proper examination of this relationship requires an accurate diagnosis of fetal asphyxia and a reliable measure of central nervous system injury.

The diagnosis of fetal asphyxia requires a blood gas and acid-base assessment to determine a significant metabolic acidosis. The clinical criteria used in many studies are indicative but not diagnostic of fetal asphyxia because of their relatively low sensitivity and high false-positive rates.[3]

The concept of a continuum of casualty[4] implies that beyond the threshold a moderate amount of asphyxia may cause a small amount of damage, whereas severe

asphyxia may cause a large amount of damage. Clinical measures of such damage can be obtained in follow-up studies with the identification of major and minor motor or cognitive handicaps or developmental delays that emerge during infancy or early childhood.

However objective measures of central nervous system injury during the newborn period are not available. In addition, less severe asphyxial insults may be significant but behavioral index may not be sufficiently sensitive to demonstrate the effect on the central nervous system.

The Brazelton[5] neonatal behavioural assessment scale was conceived as a clinical instrument for evaluation and measurement of neonatal behavior and has been reputed to provide a sensitive index of central nervous system function. Tronick[6] proposed that behavioral assessments in the newborn period may identify mild dysfunctions that are not apparent from standard neurologic examination. For example, the degree to which the infant is able to achieve, maintain, and modulate state control during both sleep and alert periods after sensory stimulation is thought to reflect the maturity and integrity of central nervous system control of the highest order.[7] Thus the newborn behavioral assessment scale, when administered by trained examiners, may provide an objective measure of minimal central nervous system injury during the neonatal period. The effect of a number of environmental stress factors on the newborn have been demonstrated with the newborn behavioral assessment scale; examples include alcohol,[8] opiates,[9] analgesics, and anesthetic agents.[10, 11]

The objective of the present study was to examine the association of biochemically determined intrapartum asphyxia in the mature fetus with newborn behavior as expressed by the newborn behavioral assessment scale 3 days and again 2 weeks after delivery.

Methods

A matched case-control study was carried out between January 1987 and June 1989. During this period, a blood gas and acid-base assessment of umbilical cord blood at delivery was performed for 3674 patients representing approximately 70% of all deliveries. The criteria of significant intrapartum fetal asphyxia was an umbilical artery buffer base value <34.0 mmol/L.[3] Fetal asphyxia was observed in 99 newborns at delivery, an incidence of 2.7%.

The group with asphyxia in this study included 51 of the 99 newborns with a significant metabolic acidosis at delivery. Newborns not included in the study were preterm newborns and newborns whose parents either did not consent to participate or who could not be seen immediately after delivery to obtain consent. There was no significant difference between the umbilical artery buffer base value of newborns in the group with asphyxia (mean umbilical artery buffer base value 30.5 ± 4.2 mmol/L) and the asphyxiated newborns not entered in the study (mean umbilical artery buffer base value 30.4 ± 3.9 mmol/L).

The control group consisted of the next newborns with an umbilical artery buffer base value >38 mmol/L, matched for gestational age and birth weight ± 200 gm whose parents consented to participation of their newborns in the study. The mean birth weight for the group with asphyxia was 3267 gm and for the control group was 3315 gm. The mean umbilical artery buffer base value for the control group was 42.2 mmol/L.

The Apgar scores at 1 and 5 minutes were recorded for each newborn. Newborn encephalopathy was documented on the basis of observations of the nurses and physicians. The criteria for the diagnosis included behavioral changes, abnormalities of tone, and seizures. Abnormalities of behavior, irritability, jitteriness, lethargy, and coma were identified by observations of spontaneous movement of the infant. Increased or decreased tone was identified during observations of posture and active and passive movement. Subtle, tonic, or clonic seizures were noted. Newborn encephalopathy was classified as mild with abnormalities of behavior, moderate in the presence of lethargy and hypotonia, and severe in the presence of seizures.

The newborn behavioral assessment scale was administered in the hospital to newborns when they were 3 days old if medically stable and again in the home 2 weeks after delivery by a research assistant who had been certified as a reliable examiner by Brazelton. The research assistant was not informed of whether the newborn infant was of the group with asphyxia or the control group. The newborn behavioral assessment scale includes 26 behavioral items (the pin-prick item was omitted) and 16 reflexes. The Lester cluster summary scores[10] were used to summarize the newborns' performance. He combined the 26 behavioral items into six summary clusters and used the 16 reflexes to generate a seventh cluster. The six behavioral clusters are: (1) habituation, response decrement to repeated auditory, visual, and tactile stimulation; (2) orientation, orienting response toward animate and inanimate stimuli, and overall alertness; (3) motor, integrated motor acts and overall muscle tone; (4) range of state, the rapidity of build-up, peak, and lability of state changes; (5) regulation of state, infants' ability to modulate their own state control; and (6) autonomic regulation, signs of physiologic stress such as tremors, startles, and changes of skin color. The seventh or reflex cluster is the total number of intact reflexes scored.

In administering the test it was difficult to obtain complete data for all the items for all subjects because

of the state control requirements. For example, habituation must be administered while the infant is asleep, and many waken after a few trials.

Statistical analysis included the Student t test. Statistical significance was $p < 0.05$.

This study was approved by an ethics review committee of the Faculty of Medicine, Queen's University.

Results

The Lester summary scores of the newborn behavioral assessment scale for the group with asphyxia and the control group administered 3 days after delivery are presented in Table I. There were no significant differences between the summary scores of the group with asphyxia and the control group. To provide a complete description of the results, average performance on the individual items, which constitute the summary scores, were compared. This more detailed analysis failed to reveal any significant differences between the two groups on individual item scores.

The Lester summary scores of the newborn behavioral assessment scale for the group with asphyxia and the control group administered 2 weeks after delivery are also presented in Table I. The summary score for range of state in the group with asphyxia was significantly lower than that in the control group and a similar trend was apparent for the motor score. A review of the individual items that constitute the summary scores identified six items for which the score of the group with asphyxia was lower than that of the control group ($p < 0.1$). In regard to the range of state, the average for all items in the group with asphyxia were lower than those in the control group, whereas in regard to motor summary, the differentiating items were pull to sit and motor maturity.

The group with asphyxia was divided into two subgroups on the basis of the severity of the metabolic acidosis. The mean umbilical artery buffer base value was 33.3 mmol/L for the group with moderate asphyxia and 27.9 mmol/L for the group with more severe asphyxia. There was no evidence that the group with more severe asphyxia had significantly lower summary scores than those of the group with moderate asphyxia.

The mean Apgar scores in the group with asphyxia were significantly lower than those in the control group at 1 minute (6.2 vs 8.2, $p < 0.0001$) and at 5 minutes (8.2 vs 9.1, $p < 0.004$). Thus an analysis of the Lester summary scores for the newborn behavioral assessment scale administered 3 days and 2 weeks after delivery in relation to Apgar scores in the group with asphyxia was carried out. Newborns with Apgar scores 0 to 3 were compared with newborns with Apgar scores 4 to 7 and Apgar scores 8 to 10 at 1 minute and 5 minutes after delivery. There were 11 newborns in the group with asphyxia with Apgar scores 0 to 3 at 1 minute after delivery. Newborns with Apgar scores 0 to 3 after delivery demonstrated a lower summary score for regulation of state ($p < 0.03$) 3 days after delivery, and a lower summary score for autonomic regulation ($p < 0.03$) 2 weeks after delivery. These differences likely reflect chance in view of the number of analyses. There were only two newborns with Apgar scores of 0 to 3 at 5 minutes after delivery. There were no significant differences between the summary scores for the newborns with Apgar scores 4 to 7 and newborns with Apgar scores 8 to 10 at 5 minutes after delivery.

There were three newborns with mild or moderate newborn encephalopathy and one newborn with severe newborn encephalopathy in the group with asphyxia. The mean umbilical artery buffer base value for this small subgroup was 25.4 mmol/L. There were no striking differences between the Lester summary scores for the newborns with encephalopathy in relation to those without encephalopathy. However, the subgroup with newborn encephalopathy tended to have lower motor, range of state, and autonomic regulation summary scores in the newborn behavioral assessment scale administered 2 weeks after delivery.

Comment

No reports have been found that used the newborn behavioral assessment scale to assess the association of biochemically determined intrapartum fetal asphyxia. This was a matched cohort study of mature newborns with similar birth weight and an equal number of growth retarded newborns in each group. This design controls for the different patterns of newborn behavior in the term infant in relation to the preterm newborns[12] and in the growth-retarded infant in relation to the normally grown newborns.[13]

Newborns of the group with asphyxia were derived from blood gas and acid-base screening of a large number of deliveries, which in general were representative of the obstetric population in this regional referral center. As anticipated, the Apgar scores of the group with asphyxia were significantly lower than those in the control group. However, only four newborns exhibited signs of newborn encephalopathy. Thus the fact that the study population does not reflect the severe end of the spectrum of intrapartum fetal asphyxia may have mitigated against our finding group differences.

Three days after delivery the Lester newborn behavioral assessment scale summary scores for the group with asphyxia were of the same order as those of the control group. This was also true when the newborns in the group with asphyxia with more severe metabolic acidosis were compared with those in the control group. Asphyxiated newborns with low Apgar scores at 1 and 5 minutes may represent a more severe asphyxial insult to the fetus. However, the summary scores of newborns with low Apgar scores were not significantly different from those of the newborns with good Apgar scores.

The results of the 3-day newborn assessment are in keeping with the contention that many newborns who have undergone an intrapartum asphyxial insult will not display signs of central nervous system injury. The protection of the central nervous system is presumably because of fetal cardiovascular and cerebral oxygen consumption compensatory mechanisms. Fetal hypoxemia results in increased arterial pressure as a result of increased vascular resistance associated with a redistribution of cardiac output. There is reduced blood flow to the pulmonary, renal, gastrointestinal circulation, and the body, and increased blood flow directed to the brain, heart, and adrenals.[14-16] Recent studies of fetal lamb indicate normal cerebral oxygen consumption will continue for some time in the presence of a relative degree of fetal hypoxia.[17]

Newborns with seizures have been shown to have less favorable newborn behavioral assessment scale scores.[18] Our four newborns with evidence of newborn encephalopathy had less favorable Lester summary scores at 2 weeks after delivery. Given this trend it is reasonable to assume that a larger sample of newborns with severe encephalopathy might have confirmed this finding.

The expression of abnormal newborn behavior because of a central nervous system asphyxial insult may be delayed. When the Lester summary scores for the newborn behavioral assessment scale administered 2 weeks after delivery were examined, the group with asphyxia in relation to the control group had a lower summary score for range of state. The group with asphyxia had lower scores for six individual items of the newborn behavioral assessment scale that are components of the range of state and motor summary scores. These differences are small and of limited statistical significance. However, the possibility of a delayed expression of the effect of an asphyxial insult of the central nervous system deserves further assessment.

The results of the present study suggest that the threshold of central nervous system injury as a result of intrapartum fetal asphyxia is at the severe end of the spectrum of asphyxia when it is expressed by objective measures of metabolic acidosis.

Sexually transmitted diseases and human immunodeficiency virus infection among women with pelvic inflammatory disease

Bente Hoegsberg, MD,[a] Ovadia Abulafia, MD,[a] Alexander Sedlis, MD,[a] Joseph Feldman, DrPH,[b] Don DesJalais, PhD,[d] Sheldon Landesman, MD,[c] and Howard Minkoff, MD[a]

Brooklyn and New York, New York

Both human immunodeficiency virus infections and pelvic inflammatory disease are sexually acquired illnesses of great consequence to women. This study was undertaken to determine if women hospitalized with pelvic inflammatory disease, in a community endemic for human immunodeficiency virus, were at high risk to be infected with human immunodeficiency virus and if human immunodeficiency virus infections altered their hospital course. One hundred ten women hospitalized with pelvic inflammatory disease in Brooklyn (in a hospital in which 2% of parturients are human immunodeficiency virus seropositive) agreed to human immunodeficiency virus testing; 15 (13.6%) were found to be seropositive. Seropositive women were significantly more likely to have an admission white blood cell count $<10,000/mm^3$ ($p = 0.001$). Human immunodeficiency virus seropositivity was not associated with a higher frequency of other sexually transmitted diseases although there was a trend toward more cases of syphilis among human immunodeficiency virus–infected women. Similarly, although there was no significant difference in rates of operative intervention (26.6% among seropositive and 8.4% among seronegative; $p = 0.058$), there was a trend toward more surgery among those who were human immunodeficiency virus infected. Women hospitalized with pelvic inflammatory disease, in a community endemic for human immunodeficiency virus, are at high risk for human immunodeficiency virus infection. More research is needed to verify a trend toward more refractory infections among human immunodeficiency virus–infected women. (AM J OBSTET GYNECOL 1990;163:1135-9.)

Key words: Human immunodeficiency virus (HIV), pelvic inflammatory disease (PID), sexually transmitted diseases (STD)

Pelvic inflammatory disease is a major cause of acute and chronic morbidity among women of reproductive age. Although the exact incidence of pelvic inflammatory disease is unknown, it has been estimated that by the year 2000 one of every 20 women who was 15 years old in 1970 will have had at least one episode of pelvic inflammatory disease.[1] The risk of acquiring pelvic inflammatory disease is associated with young age, increased numbers of sexual partners, and low

socioeconomic status. Infections with human immunodeficiency virus (HIV) and other sexually transmitted diseases (STDs) are increasing among the same groups.[2, 3] Since these infections, as well as pelvic inflammatory disease, are sexually transmitted, it is possible that women who have pelvic inflammatory disease are at risk for HIV infection. Further, coincident infection with HIV has already been shown to influence the course of other STDs and to be associated with increases in mortality from a variety of non–"acquired immunodeficiency syndrome" infections.

The following cross-sectional study was undertaken to assess the prevalence of HIV infection among women hospitalized with pelvic inflammatory disease in a community endemic for HIV[5] and to determine if such women, who are also HIV antibody positive, have a higher prevalence of other STDs and are more severely ill.

Material and methods

Women admitted to Kings County Hospital Center between November 1987 and October 1988 who fulfilled published criteria for the diagnosis of pelvic inflammatory diseases (Table I) were eligible to participate in the study. Participants signed a study consent form, as well as a New York State consent form for HIV antibody testing. The study protocol was approved by the hospital institutional review board and the New York City Health and Hospital Corporation.

On admission diagnostic tests for STDs were performed. Saline solution washings from the posterior fornix were examined microscopically for the presence of *Trichomonas vaginalis, Candida albicans,* and bacterial vaginosis, which was diagnosed when the pH was alkaline, clue cells were present, and the "whiff" test was positive. Additionally, samples from the cervix were cultured for *Chlamydia trachomatis* according to a technique described elsewhere.[7] Specimens from the cervix, urethra, and anus were cultured for *Neisseria gonorrhoeae.* Samples from the cervix were cultured for herpes simplex virus.[7] All patients had Papanicolaou smears, which were assessed for koilocytes, multinucleation, and other changes indicating human papillomavirus infection.[8] Blood was drawn for rapid plasma reagin tests (followed, when positive, with fluorescent treponemal antibody tests) and HIV antibodies. HIV serologic testing was performed at the New York City Department of Health laboratory. Samples repeatedly positive by enzyme-linked immunosorbent assay were confirmed by Western blot.

Patients underwent detailed interviews about demographic factors, sexual practices, and drug use. A cross-sectional comparison between HIV-positive and HIV-negative subjects was performed for STDs, physical findings, and demographic characteristics.

The HIV antibody status of study subjects was not known by treating physicians. All STDs, including pelvic inflammatory disease, were treated per Centers for Disease Control guidelines.[9]

Statistical analysis. Differences between HIV-positive and HIV-negative patients were compared with Fisher's exact test. All statistical tests were two-tailed. To compensate for asymmetry and highly discrete data, a mid p value was obtained by subtracting half of the probability of the observed statistic from the exact value.[9] Odds ratios and their 95% confidence intervals were computed by exact methods with conditional maximum likelihood estimations.[10]

Results

During the 12-month study period 190 eligible patients were admitted with pelvic inflammatory disease. Of these, 144 were offered entry into the study. The remainder (n = 46) had signed out against medical advice or were otherwise unavailable (discharged before study personnel could approach them or admitted at a time when study personnel were not available). Of the 144 patients who were offered entry, 112 (78%) accepted. Two were later excluded because they had ectopic pregnancies. The majority of patients who refused to participate in the study stated (1) that they did not want to know their HIV antibody status or (2) that they had to ask their boyfriends first.

Fifteen of the 110 patients (13.6%; 95% confidence interval, 7.9% to 21.5%) who entered the study were HIV antibody positive. There was no significant difference in the mean age (28.5 ± 6.9 vs 28.1 ± 4.7 years) or parity (1.8 ± 1.3 vs 1.2 ± 1.2) between seropositive and seronegative patients. Among HIV-positive patients two were parenteral drug users, two were sex partners of parenteral drug users, and four both used parenteral drugs and had drug-using partners. Two additional patients came from countries where heterosexual spread is known to occur. Five women acknowledged no risks and had no signs of

Table II. Hospital course of HIV-antibody-positive and HIV-antibody-negative patients

	HIV status

Admission temperature >38°C	13/15 (86%)	76/95 (80%)	89/110 (81%)	0.73	4.62	0.37-11.37
Tuboovarian abscess	4/15 (22.6%)	13/95 (13.7%)	17/110 (15.5%)	0.24	2.27	0.55-8.14
Surgery	4/15 (26.6%)	8/95 (8.4%)	12/110 (10.9%)	0.058	3.89	0.89-15.29

Table III. STDs among HIV-antibody-positive and HIV-antibody-negative patients

	HIV status					
	Positive	*Negative*	*Overall*	*p Value*	*Odds ratio*	*95% Confidence interval*
Chlamydia	15% (2/13)	16% (14/89)	16% (16/102)	0.99	0.97	0.13-4.49
Gonorrhea	33% (5/15)	25% (23/91)	27% (28/106)	0.53	1.47	0.42-4.78
Candida albicans	7% (1/14)	14.1% (12/85)	13.1% (13/99)	0.68	0.47	0.02-3.11
Human papilloma virus (Papanicolaou smear)	29% (4/14)	25% (22/87)	26% (26/101)	0.75	1.18	0.29-4.09
Herpes simplex virus (culture)	8.33% (1/12)	1.96% (1/31)	3.17% (2/63)	0.35	4.4	0.11-180.4
Trichomonas	13% (2/15)	12% (11/33)	12% (13/108)	0.99	1.15	0.16-5.32
Bacterial vaginosis	14% (2/14)	11% (10/91)	11.4% (12/105)	0.66	1.35	0.18-6.42
Positive VDRL and FTA tests	53% (8/15)	34% (31/92)	36% (39/107)	0.16	2.23	0.72-7.04
Hepatitis	7% (1/15)	2% (2/91)	3% (3/106)	0.37	3.13	0.10-43.49

VDRL, Venereal Disease Research Laboratory; *FTA*, fluorescent treponemal antibody.

intravenous drug use (needle tracks). In sum heterosexual transmission was the most likely mode of transmission in 9 of 15 (60%) patients.

On admission 40% (6/15) of the HIV-positive patients and 89% (85/95) of the HIV-seronegative patients had a white blood cell count of ≥10,000/mm³ ($p < 0.001$) (Table II). A temperature >38° C on admission was found in 86% (13/15) and 80% (76/95) of seropositive and seronegative patients, respectively ($p = 0.73$). The mean hospital stay was 5.8 days for seropositive patients and 5.6 days for seronegative patients ($p = 0.75$). Four of the 15 seropositive women (26.6%) had tuboovarian abscesses confirmed ultrasonographically, compared with 13 of 95 seronegative women (13.7%) ($p = 0.24$). Thus 4 of 17 women with tuboovarian abscesses (23.5%) were seropositive, compared with 11 of 93 women without tuboovarian abscesses (11.8%). Four of the 15 seropositive women (26.6%) had persistent fevers that were refractory to antibiotics and they required surgery: salpingo-oophorectomy ($n = 2$), total abdominal hysterectomy and bilateral salpingo-oophorectomy ($n = 1$), and laparoscopy ($n = 1$). Eight of the seronegative women (8.4%) had surgery: total abdominal hysterectomy and bilateral salpingo-oophorectomy ($n = 5$), unilateral salpingo-oophorectomy ($n = 2$), and laparoscopy ($n = 1$). The difference in the proportion of patients undergoing operation (26.6% vs 8.4%) by HIV status missed attaining statistical significance at the traditional level ($p = 0.058$; 95% confidence interval, 0.89 to 15.25).

As can be seen in Table III there was no significant difference between seropositive and seronegative patients in rates of STDs, although the difference in syphilis rates (53% vs 34%; odds ratio, 2.23; 95% confidence interval, 0.72 to 7.043) approached significance ($p = 0.16$).

Comment

Pelvic inflammatory disease, because of its prevalence, cost, and consequent morbidity, is one of the most important STDs among women. Sexual risk behaviors are clearly associated with the acquisition of both pelvic inflammatory disease and HIV. In our study of 110 in-

patients with pelvic inflammatory disease in a community that is endemic for HIV we indeed found a high rate (13.6% with a lower limit of 8%) of HIV infection, particularly among women with evidence of tuboovarian abscesses (23.5%) or white blood cell counts $<10,000/mm^3$ (47.4%). The rates are higher than previously reported from women at the same institution who were giving birth[12] or who had cervical dysplasia.[13]

HIV infections among women are being acquired increasingly through heterosexual contact. This finding was also apparent in our study. Almost two thirds of patients' putative risk for HIV infection was sexual contact. However, parenteral drug use continued to be an important risk factor with more than half of the patients either using intravenous drugs or having as their risk factor heterosexual contact with an intravenous drug user. The rate of HIV infection, even among that cohort with no intravenous drug use or sexual exposure to intravenous drug users, was sufficiently high to warrant routine counseling and offering of HIV testing to all inpatients with pelvic inflammatory disease in this community. As noted, groups at particularly high risk for HIV infection include those with a tuboovarian abscess (23.5%) and those with white blood cell counts $<10,000/mm^3$ (9/19, 47.4%).

The low white blood cell count found among women who otherwise fulfilled criteria for pelvic inflammatory disease could reflect an HIV-mediated blunting of the normal leukocytosis associated with acute pelvic inflammatory disease. HIV infections are associated with a lymphophopenia that could have contributed to this finding.

The clinical course of pelvic inflammatory disease among HIV-infected women has not been previously described. Although the in-hospital course of patients in our study did not vary in a statistically significant manner with serologic status, there was a trend toward more tuboovarian abscesses and more instances of operative intervention among seropositive women, and our study design might mask other subtle differences. If, for example, HIV-infected women have more severe cases of pelvic inflammatory disease, it would be more difficult to detect such an effect in a population consisting exclusively of inpatients. Thus, if HIV-infected women with pelvic inflammatory disease are more likely to require in-hospital care, our design would not detect that effect. Although the design and small sample size limit our ability to distinguish significant differences, HIV-seropositive women were at least twice as likely to have tuboovarian abscess and to undergo surgery. Given the possibility of more refractory pelvic inflammatory disease, it might be prudent to treat all known HIV-infected women with pelvic inflammatory disease aggressively, with consideration given to inpatient treatment for all such women.

The prevalence rate of syphilis among HIV seropositive women in this population was 53%. Although not quite statistically significantly higher than that of seronegative women in this study, the high rate of syphilis among HIV-positive patients is in concordance with that reported elsewhere.[14] Antecedent infection with syphilis or other ulcerative diseases has been reported to enhance acquisition and transmission of HIV.[15] Coincident infection with HIV can also modify the course of diseases such as syphilis. In our study population patients with pelvic inflammatory disease who were HIV seropositive did not have a significantly different pattern of associated STDs, other than syphilis, or vaginitis than that seen among HIV-seronegative patients. The rate of STDs among all patients, however, was quite high for infections ranging from human papillomavirus to hepatitis.

A potential bias in the study related to reported HIV prevalence involves ascertainment in recruitment. We do not know the characteristics of the patients who elected not to participate. However, study personnel strongly believed that many of the patients who elected not to participate were at very high risk of HIV infection because of apparent drug use and noncompliance during admission. Additionally patients who were not eligible because they signed out against medical advice before completing therapy for pelvic inflammatory disease may be at particularly high risk. It is possible therefore that the rate of HIV infection may have been understated.

In sum, women from communities that are endemic for HIV, who are treated in the hospital for pelvic inflammatory disease, represent a group at high risk for HIV infections. Further research is needed to evaluate a possible trend toward more refractory pelvic inflammatory disease among HIV-infected women.

We acknowledge Tonya Dotson's contributions to data collection.

The effect of large uterine fibroids on urinary bladder function and symptoms

Rami Langer, MD, Abraham Golan, MD, Menachem Neuman, MD, David Schneider, MD, Ian Bukovsky, MD, and Eliahu Caspi, MD

Zerifin, Israel

Fourteen patients with large uterine fibroids and urinary symptoms were treated with monthly injections of [D-Trp^6]-luteinizing hormone–releasing hormone microcapsules. The average uterine size before treatment was 728 ml; it dropped to 323 ml (a drop of 55%) after treatment. Urinary symptoms of diurnal frequency disappeared in 11 of 12 patients ($p < 0.005$) after the reduction of uterine size. Urgency decreased in 11 of 13 ($p < 0.005$) and nocturia in eight of 10 ($p < 0.02$). No differences were found before and after treatment in the symptoms of urge incontinence and stress incontinence in the cystometric and urethral pressure profile measurements. Urinary symptoms of frequency, urgency, and nocturia may be caused by the direct pressure exerted on the bladder by the enlarged uterus. Symptoms of urge incontinence and stress incontinence deserve a more specific treatment as they are not related to uterine size. (AM J OBSTET GYNECOL 1990;163:1139-41.)

Key words: Uterine fibroids, gonadotropin-releasing hormone analogs, bladder symptoms

Patients who have large pelvic tumors frequently have evidence of pressure on the urinary bladder giving rise to symptoms of frequency, urgency, and incontinence. These symptoms are common with large uterine fibroids, which are the most common tumors of the female pelvis. Removal of these fibroids may result in relief of the patients' urinary symptoms, as suggested by some.[1] On the other hand, surgical removal of the uterus may cause further exacerbation of the urinary symptoms because of bladder denervation.[2] Others[3] state that urinary symptoms are very rarely the result of direct uterine pressure on the bladder and, as such, urinary symptoms are a most inadvisable indication for hysterectomy.

The purpose of this study was to assess both objectively and subjectively the influence of large uterine fibroids on the urinary bladder in a model in which these tumors could be reduced in size by nonsurgical means.

Material and methods

At Assaf Harofeh Medical Centre we treat patients with large uterine fibroids scheduled for operation with gonadotropin-releasing hormone (GnRH) analogues for 2 months beforehand to reduce the uterine size; this results in less bleeding before and during operation. From these patients we selected 14 (uterine size >17 weeks of gestation) with lower urinary tract symptoms.

Uterine size was determined by ultrasonography according to the formula for ellipsoid tumors, $V = 4/3R_1 \times R_2 \times R_3 \times \text{II}$.[4] Each patient had two monthly intramuscular injections of [D-Trp^6]-luteinizing hormone–releasing hormone microcapsules (Decapeptyl, 3.2 mg; Ferring, Kiel, Federal Republic of Germany). The injections were given at 2 months and 1 month before operation. Ultrasonographic examinations were performed before the GnRH analog treatment and just before operation.

Before the first injection of the GnRH analog and again immediately before operation each patient had a full history taken and the following urinary symptoms were recorded: diurnal frequency, nocturia, urgency, urge incontinence, and stress incontinence.

The urodynamic investigation included cystometry and uroflowmetry, performed by the urinary investigation system 5000 (Lectromed, St. Peter, Jersey, Channel Islands), with saline solution used as the filling substance at room temperature and at an infusion rate of 100 ml/sec. Measurements were made with the patient in the supine and standing positions. Urethral profile pressures were performed with the dual Gaeltec microtransducer catheter (Glasgow). These tests at rest and on stress were described elsewhere.[5] Pressure transmission ratios[6] were calculated from the stress profile at four equidistant points along the functional length of the urethra. Diurnal frequency was defined as the passage of urine six or more times during the day or twice or more at night. The methods, definitions, and units conform to the standards proposed by the International Continence Society.[7] The statistical method used was McNemar's paired χ^2 test.

Table III. Urethral pressure profile before and 2 months after decapeptyl treatment ($N = 14$)

	Before treatment	*After treatment*
Absolute length (cm)	49.8 ± 5.2	47.9 ± 6.1
Functional length (cm)	44.7 ± 4.5	46.1 ± 4.1
Maximal urethral pressure	58.6 ± 10.4	57.3 ± 11.7
Maximal urethral closure pressure (mm H_2O)	52.4 ± 13.1	50.3 ± 12.8
Pressure transmission (ratio %)		
Q_1	92.8 ± 3.2	94.1 ± 2.6
Q_2	98.7 ± 6.3	99.1 ± 5.3
Q_3	99.8 ± 4.5	98.1 ± 5.1
Q_4	71.7 ± 9.8	73.1 ± 6.7

p = NS.

Results

The mean age of the patients was 44.2 years (range, 39 to 50), and mean parity was 2.6 (range, 1 to 4). Before the [D-Trp^6]-LH-RH treatment, the average uterine size, as measured by ultrasonography, was 728 ml; this dropped to 323 ml after 2 months of treatment (drop of 55%). Clinically a significant decrease (Table I) in the incidence of diurnal frequency, urgency, and nocturia was found after 2 months of [D-Trp^6]-LH-RH treatment ($p < 0.005$, <0.005, and <0.02, respectively). Symptoms of urge incontinence and stress incontinence were not affected by the decrease in uterine size.

Urodynamically, there were no significant differences between the pretreatment and posttreatment values of capacity, residual volume, and pressure rise on filling or standing, in the maximal voiding pressure, and in the peak flow rates (Table II).

Urethral pressure curves (Table III) showed no significant differences regarding values of urethral length, closure pressure, and pressure transmission ratios before and after treatment with GnRH analogs.

Comment

Treatment of uterine fibroids with GnRH analogs, their mode of action, indications, and results are well documented.[8] We treat patients with large fibroids with GnRH analogues 2 months before operation to reduce uterine size, facilitate surgery, and reduce blood loss. This reduction in uterine size (55% of the initial volume) enabled us to examine the "net" effect of the large uterus on the bladder in patients with urinary symptoms. The commonly held view that surgical removal of the enlarged uterus may cause disappearance of these urinary symptoms is controversial, mainly because hysterectomy by itself may cause urinary disturbances.[2,9] In a recent report[10] we showed that abdominal hysterectomy for benign conditions in patients without urinary symptoms does not cause urinary symptoms after operation.

In this preliminary study we proved that patients with large uterine fibroids and urinary symptoms had a significant reduction in symptoms of diurnal frequency, urgency, and nocturia merely by reducing the uterine size. One may assume that these symptoms are caused by the direct pressure exerted on the bladder by the enlarged uterus. On reduction of uterine size we found no changes in either cystometric, uroflowmetry, or urethral profile pressure measurements or in the symptoms of urge and stress incontinence. These symptoms deserve more specific treatment because they are most probably unrelated to uterine size.

The natural history of thrombocytopenia associated with preeclampsia

Vern L. Katz, MD, John M. Thorp, Jr., MD, Lynda Rozas, BA, and Watson A. Bowes, Jr., MD
Chapel Hill, North Carolina

Sixty-one of 375 women with hypertension and preeclampsia in a 48-month period had thrombocytopenia. By postpartum day 3, 90% of these women had rising platelet counts, and by day 4, 59 of 61 women had counts >100,000/mm³. The two exceptions had other pathologic conditions in addition to preeclampsia. Thrombocytopenia associated with preeclampsia should resolve by postpartum day 4. (Am J Obstet Gynecol 1990;163:1142-3.)

Key words: Thrombocytopenia, preeclampsia, platelets

Preeclampsia may be associated with a low platelet count.[1] Delivery leads to resolution of preeclampsia with removal of agents that may initiate endothelial damage and platelet consumption.[1, 2] Thus thrombocytopenia should resolve after delivery. The purpose of this study is to clarify the time course of thrombocytopenia associated with preeclampsia.

Methods

We reviewed the records of obstetric patients with diagnoses of hypertension or preeclampsia at North Carolina Memorial Hospital, a university teaching hospital, over a consecutive 48-month period. Hypertension was defined as a blood pressure of 140/90 mm Hg taken on two occasions at least 6 hours apart. Preeclampsia was defined as hypertension and proteinuria (300 mg/24 hours or two measurements of 2+ on dipstick). Severe preeclampsia was diagnosed by one of the following parameters: eclampsia, pulmonary edema, >4 gm of proteinuria in 24 hours, oliguria, or diastolic blood pressure >110 mm Hg. Thrombocytopenia was omitted as a diagnostic criteria for severe preeclampsia. The lowest platelet count in a given day was used for our assessment. A rising platelet count was defined as a platelet elevation >15% from the previous day's count.

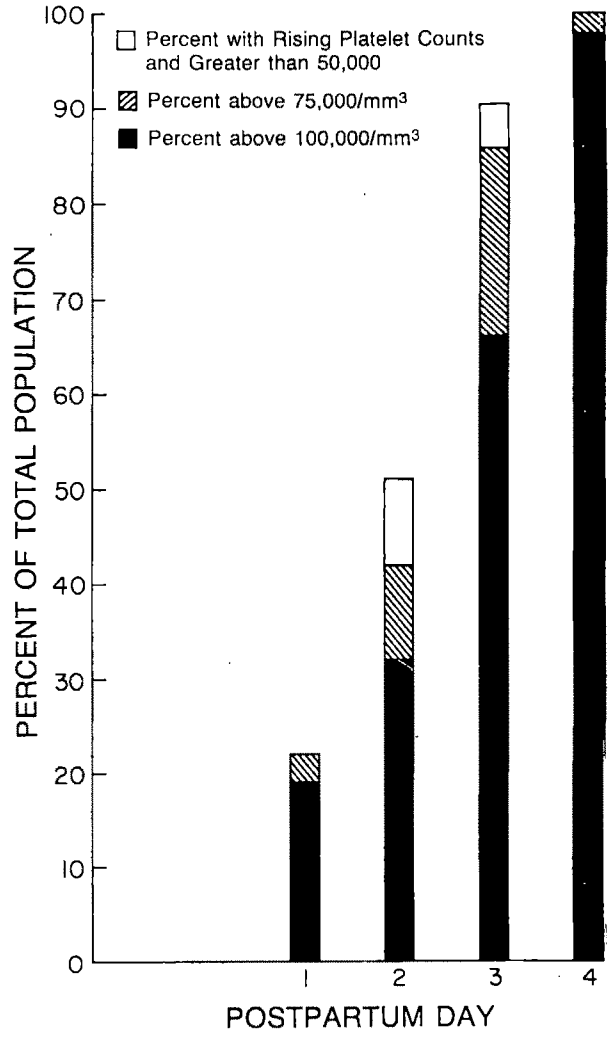

Fig. 1. Resolution of thrombocytopenia associated with preeclampsia.

Results

Three hundred seventy-five patients who were delivered during the study period were given a diagnosis of preeclampsia or hypertension. Preeclampsia was confirmed in 237 patients. Platelet counts were >150,000/mm³ in 116 women, 31 of whom had severe preeclampsia. Forty women had platelet counts between 120,000/mm³ and 150,000/mm³; nine had severe preeclampsia. Twenty patients had counts between 100,000/mm³ and 120,000/mm³, and two had severe disease. Seventeen of these 20 patients had rising platelet counts by postpartum day 2. Three patients did not have platelets measured after postpartum day 1.

Sixty-one patients with preeclampsia had platelet counts <100,000/mm³; 16 of these women had severe disease. The resolution of their thrombocytopenia is shown in Fig. 1. On postpartum day 2, 51% of women had rising platelet counts. On postpartum day 3, 90% had rising counts, and 86% of women had counts >75,000/mm³. By postpartum day 4, 59 of 61 women had rising counts and all but four women had counts >100,000/mm³. The two exceptions included a woman with chronic renal disease and normal platelet counts at delivery, but a decline to 87,000/mm³ on postpartum day 3. Her count rose to 118,000/mm³ on postpartum day 6. This patient had normal liver function tests and no evidence of hemolysis. The other patient who had no rise in platelet count had *Proteus mirabilis* sepsis, disseminated intravascular coagulopathy, and adult respiratory distress syndrome. Her platelet counts ranged between 63,000/mm³ and 96,000/mm³ on postpartum days 1 through 7.

Comment

In this series only two women did not have rising platelet counts by postpartum day 4. Both of the exceptions were atypical and had thrombocytopenia, most likely from factors other than preeclampsia. Thus if a patient with preeclampsia does not have a rising platelet count by postpartum day 3, and a count approaching 100,000/mm³ by postpartum day 4 in the absence of other pathologic conditions, she is beyond the expected time course of thrombocytopenia associated with preeclampsia.

Continuing controversy in alloimmune thrombocytopenia: Fetal hyperimmunoglobulinemia fails to prevent thrombocytopenia

Umberto Nicolini, MD,[a] Yuen Tannirandorn, MD,[a] Pedro Gonzalez, MD,[a] Nicholas M. Fisk, MD,[a] Jeremy Beacham, MSc,[c] Elizabeth A. Letsky, MD,[a] and Charles H. Rodeck, MD[a]

London, England

Two patients with severe alloimmune thrombocytopenia were managed by weekly intrauterine platelet transfusions at 25 to 36 weeks. In one patient high-dose immunoglobulin was also administered weekly to the mother, and high maternal and fetal immunoglobulin levels were achieved. Fetal platelet counts were similar in both patients. The only variable that affected fetal platelet concentration was the posttransfusion platelet count from the previous transfusion. (AM J OBSTET GYNECOL 1990;163:1144-6.)

Key words: Alloimmune thrombocytopenia, intracranial hemorrhage, platelet transfusion

Perinatal alloimmune thrombocytopenia is associated with a perinatal mortality of 10% to 15% and severe neurologic abnormalities in up to 25% of infants, the majority of which are attributable to intracranial hemorrhage.

Ultrasonography-guided fetal blood sampling has been used in this condition to determine the platelet count and platelet antigen status at 20 to 22 weeks and again before delivery.[1] In the presence of thrombocytopenia at 37 to 38 weeks fetal intravascular platelet transfusion was performed before elective delivery. However, this strategy does not address the problem of the prevention of intracranial hemorrhage earlier in pregnancy. More recently, increases in fetal platelet counts have been reported by Bussel et al.[2] after maternally administered immunoglobulin.

We report here on two patients with severe perinatal alloimmune thrombocytopenia, managed by weekly in utero platelet transfusions; one of them also received a maternal intravenous infusion of high-dose immunoglobulin.[2]

Case reports

Two patients who had previously given birth to infants with severe perinatal alloimmune thrombocytopenia were studied. Initial fetal blood sampling was performed under ultrasonographic guidance at 26 and 25 weeks' gestation in patients A and B, respectively, by means of a 20-gauge needle. Platelet count was 28×10^9/L in patient A and 4×10^9/L in patient B.

In patient A weekly in utero transfusions of platelet antigen-1–negative concentrated platelets were performed on seven occasions. In patient B high-dose immunoglobulin (Sandoglobulin, Sandoz Pharmaceuticals, 1 gm/kg/day) was given intravenously to the mother at weekly intervals. However, after a second fetal blood sampling at 27 weeks that revealed a low platelet count, a regimen of weekly in utero transfusions of platelet antigen-1–negative concentrated platelets was adopted. The platelet antigen-1–negative donor platelet concentrations ranged from 781 to 1743 $\times$ 10^9/L and volume was 2 to 110 ml.

Serial pretransfusion and posttransfusion platelet counts for each patient are shown in Fig. 1.

Maternal and fetal blood samples were collected for determination of immunoglobulin concentration in both patients at the time of fetal transfusions (i.e., 6 days after maternal administration of immunoglobulin in patient B).

Maternal immunoglobulin levels were above the normal range on seven of eight occasions in patient B (median, 23.6 gm/L; range, 8.7 to 25.2), whereas in patient A they were always within the normal range (median, 5.1 gm/L; range, 4.4 to 7.4) (Mann-Whitney test, $p = 0.005$). Fetal immunoglobulin levels were above our normal range on all occasions in patient B after maternal administration of immunoglobulin, as opposed to normal values in patient A (Fig. 2).

Pretransfusion platelet counts correlated significantly with the posttransfusion counts from the previous transfusion (Pearson correlation coefficient, $r = 0.729$, $p = 0.007$) and were similar in patient A (median, 29.5×10^9/L; range, 18 to 44) and patient B (median, 30.0×10^9/L; range, 7 to 63) (Mann-Whitney test, $p = 0.886$).

The median rate of fall in platelet concentrations between transfusions was similar in both patients (23.6×10^9/L/day; range, 6.0 to 28.3 in Patient A and

18.4 × 10^9/L/day; range, 10.0 to 39.4 in patient B; Mann-Whitney test, $p = 0.833$).

Neonates were delivered in good condition at 32 (case A) and 35 weeks (case B) with no signs of hemorrhage and a normal platelet count. Neither baby required postnatal platelet transfusions.

Both children are thriving and well, at ages 2 years (case A) and 6 months (case B).

Comment

Serial platelet transfusions appear effective in minimizing fetal thrombocytopenia in the third trimester in severe perinatal alloimmune thrombocytopenia and in preventing in utero intracranial hemorrhage. However, intrauterine transfusions carry a small procedure-related risk that by extrapolation from series of Rh-alloimmunized patients might be estimated around 2% to 4%. In this regard the recent series of seven patients reported on by Bussel et al.,[2] describing improvement in fetal platelet counts with maternally administered immunoglobulin, underlines the potential for a more conservtive treatment. However, five of seven had platelet concentrations $<100 \times 10^9$/L with two of these below 50×10^9/L. Failure of transplacental passage of immunoglobulins might explain the inconsistent results with this treatment. Indeed the immunoglobulin G levels in the fetal blood in the series of Bussel et al. were mostly within the normal range. On the contrary, transplacental passage was confirmed in our case B by high immunoglobulin concentrations in all the fetal samples, but no effect was demonstrated on platelet counts before each transfusion or in the rate of fall. This may be due to the following: (1) platelet antibodies are complement fixing and therefore Fc receptor blockade may not be adequate in preventing platelet destruction; (2) the placenta may block or alter the functional capacity of exogenous immunoglobulins.

In conclusion, in severe perinatal alloimmune thrombocytopenia adequate elevation of the fetal platelet count to prevent intracranial hemorrhage is more effectively achieved by platelet transfusions. It is not known how early in pregnancy intracranial hemorrhage can occur, although experience in some cases suggests that it may happen before 28 weeks of pregnancy. Since fetal pretransfusion platelet counts depend on the previous posttransfusion level, transfusion should aim for maximal elevation in platelet concentration.

Low fetal risks in pregnancies associated with idiopathic thrombocytopenic purpura

Robert F. Burrows, MD, and John G. Kelton, MD
Hamilton, Ontario, Canada

Idiopathic thrombocytopenic purpura and pregnancy are commonly associated. In this article we describe our experience in the management of 61 infants born to 50 mothers with confirmed idiopathic thrombocytopenic purpura. The focus was the neonatal cord platelet count, the parameter of greatest interest to obstetricians. None of the 61 infants had morbidity or mortality as a consequence of the thrombocytopenia. Only three of 61 infants (4.9%) had a cord platelet count that was $<50 \times 10^9$ per liter. Although 66% of the infants had a further fall in the platelet count after birth, in all the thrombocytopenia could readily be corrected. Neither maternal platelet count, maternal treatment with corticosteroids, maternal platelet-associated immunoglobulin G level, nor maternal splenectomy could be used to predict neonatal thrombocytopenia. Fetal scalp platelet sampling was likely to lead to an erroneous decision. The rareness of a poor neonatal outcome raises the question of whether obstetric interventions are justified for every pregnant patient with idiopathic thrombocytopenic purpura. (Am J Obstet Gynecol 1990;163:1147-50.)

Key words: Idiopathic thrombocytopenic purpura, pregnancy, maternal and neonatal thrombocytopenia

Idiopathic thrombocytopenic purpura is a common disease of young women. As a result, the management of idiopathic thrombocytopenic purpura during pregnancy is a clinical problem often faced by physicians. The pathophysiology of idiopathic thrombocytopenic purpura has become better understood in recent years: the thrombocytopenia is caused by an immunoglobulin G (IgG) antiplatelet autoantibody that causes platelet destruction.[1-3] Because IgG is transported across the placenta, some infants born to mothers with idiopathic thrombocytopenic purpura will be thrombocytopenic.[4,5] However, not every infant is affected and within the affected group, the degree of thrombocytopenia can vary dramatically, ranging from mild to severe. Furthermore, several years ago we noted that often the most severe thrombocytopenia does not occur until several days after delivery.[6,7] This observation has important implications for obstetricians because in some reports the recommendations concerning delivery were made on the basis of the platelet nadir. Such an approach will not produce an accurate estimate of the true hemostatic risk at the time of delivery.

6/1/22433

Uncertainty surrounding the infant's platelet count has led to a number of strategies to prevent or predict infant thrombocytopenia. For example, because of case reports that describe intracranial hemorrhage in thrombocytopenic neonates, many obstetricians recommend the delivery of idiopathic thrombocytopenic purpura mothers by cesarean section.[7,8] However, this approach will lead to many unnecessary cesarean sections, which themselves can result in morbidity.

The central question for the obstetrician making decisions concerning the optimal mode of delivery is the risk of severe neonatal thrombocytopenia at the time of delivery. For this reason, we analyzed our experience with idiopathic thrombocytopenic purpura in pregnancy with the focus moving from the postdelivery platelet nadir to the neonatal cord platelet count. Our reasoning was that the cord platelet count would be the best estimate of the true and immediate risk to the infant at the time of delivery. We found that the clinical impact of idiopathic thrombocytopenic purpura in pregnancy was modest: severe thrombocytopenia at delivery is distinctly uncommon. Furthermore, investigations such as fetal scalp platelet sampling are more likely to lead to unnecessary treatment than to no intervention at all.

Material and methods

The study was a retrospective analysis of all pregnant patients with idiopathic thrombocytopenic purpura delivered of infants in Hamilton, Ontario, Canada, from January 1980 to December 1989. A patient was con-

Table I. Maternal platelet count (× 10^9 per liter) and their neonates' cord platelet counts (× 10^9 per liter)

Maternal platelet count	*No.*	*Neonatal cord platelet count*			
		<50	*51-100*	*101-150*	*151+*

<50	5	0	0	2	3

*One set of twins.

sidered to have idiopathic thrombocytopenic purpura if she had a history of thrombocytopenia with onset before the index pregnancy. This definition was used to ensure that we did not include patients with incidental thrombocytopenia of pregnancy, a condition frequently confused with idiopathic thrombocytopenic purpura and one that does not impact on the mother or her infant.[9] The clinical diagnosis of idiopathic thrombocytopenia was made on the basis of the following criteria: (1) isolated thrombocytopenia without another hematological abnormality; (2) no secondary cause for the thrombocytopenia (hypersplenism, lymphadenopathy, systemic lupus erythematosus); and (3) a negative history for the ingestion of medication that could cause thrombocytopenia. Hamilton has three hospitals in which approximately 6000 deliveries are performed per year. All medical records from the three hospitals coded for thrombocytopenia and pregnancy were reviewed to identify those pregnancies that were complicated by idiopathic thrombocytopenic purpura.

On the basis of an analysis of the idiopathic thrombocytopenic purpura literature, we reviewed our experience with the following potential predictors of neonatal risk: maternal platelet count, maternal platelet associated IgG level, previous maternal splenectomy, steroid therapy, and fetal scalp sampling. Platelet count determinations were performed on an ethylenediamine tetraacetic acid anticoagulated specimen with a Coulter Counter (Coulter Electronics, Hialeah, Fla.). The mother or infant was said to have thrombocytopenia if the platelet counts were <150 × 10^9 per liter. Maternal platelet-associated IgG was quantitated with an immunoradiometric assay.[10] A platelet associated IgG level >5.5 fg IgG per platelet was considered abnormal.

Performance of scalp sampling. The fetal scalp blood sampling for measurement of the fetal platelet count was performed with the technique and modifications that we have described.[11] In brief, after therapeutic or spontaneous rupture of the membranes the fetal scalp was dried and a small nick was made in the scalp with the sterile razor included in the fetal blood gas kit. An ethylenediamine tetraacetic acid anticoagulant capillary sample was collected and the platelet count was determined on this sample with an automated particle counter, with the result confirmed by phase microscopy.

Results

During the study period, 50 patients with idiopathic thrombocytopenic purpura were delivered of infants in our hospitals. These 50 women had 60 pregnancies and were delivered of 61 infants.

Maternal outcome. As shown in Table I, 76.7% of mothers had thrombocytopenia at delivery and 41.7% had a platelet count <100 × 10^9 per liter. There was no serious morbidity in any of these women. Sixteen of the patients (26.7%) were receiving corticosteroids at the end of the pregnancy. No other therapy was given. Nine of the patients (18.0%) had a previous splenectomy. These women with a history of previous splenectomy were delivered of a total of 13 infants. In the entire group the cesarean section rate was 35.0% (21 of 60).

Infant outcome. The 61 infants had cord platelet counts that ranged from 24 to 420 × 10^9 per liter. A total of 52 infants (85.2%) had a cord platelet count >150 × 10^9 per liter. Three (4.9%) had a cord platelet count between 101 and 150 × 10^9 per liter. Three infants (4.9%) had a cord platelet count between 51 and 100 × 10^9 per liter and three (4.9%) had a cord platelet count <50 × 10^9 per liter (Table I). No infant had serious bleeding.

For 21 infants (34.4%) the cord platelet count (day 0) was the lowest platelet count that occurred, whereas in 40 (65.6%) of the neonates there was a further fall in the platelet count after birth. A total of 33 (54.1%) experienced their platelet nadir by day 1 or 2. Because of a further fall in platelet count after delivery, five infants required intravenous IgG. There was no evidence of serious morbidity in any infant. The neonatal platelet count had stabilized or had begun to rise in all infants by day 7.

Four of the infants with cord platelet counts <150 × 10^9 per liter were delivered by cesarean section and five were vaginally delivered. Three infants had cord platelet counts <50 × 10^9 per liter; two were vaginally delivered and the other was delivered by cesarean section because of obstetric reasons (primigravida breech presentation). None of the three had bleeding.

Prediction of infant thrombocytopenia. There was no test or maneuver that could predict neonatal thrombocytopenia. There was no correlation between the maternal platelet count and the cord platelet count at delivery (Table I). The neonatal cord platelet count was $<150 \times 10^9$ per liter in six of 26 infants (23.1%) whose mothers had a platelet count of $<100 \times 10^9$ per liter (sensitivity, 66.7%; specificity, 61.5%; positive predictive value 23.1%; and negative predictive value, 91.4%). The risk of more severe thrombocytopenia in infants, defined as a cord platelet count $<50 \times 10^9$ per liter was similar for those infants of mothers whose platelet count was $>100 \times 10^9$ per liter, compared with those mothers whose platelet counts were $<100 \times 10^9$ per liter (5.7% and 4%, respectively).

The level of platelet-associated IgG was measured in 46 pregnancies. Eight mothers had elevated platelet associated IgG, but infant cord thrombocytopenia occurred in only two infants, giving a sensitivity of 22.2%, a specificity of 83.8%, a positive predictive value of 25%, and a negative predictive value of 81.6%.

The risk of thrombocytopenia for the infants born to mothers treated with corticosteroids was the same as the risk for the infants born to mothers not treated with corticosteroids, 25% (95% CI, 3.8% to 46.2%), compared with 11.1% (95% CI, 1.9% to 20.3%).

One (7.7%) of the infants born to mothers who had undergone splenectomy had thrombocytopenia.

Fetal scalp sampling was attempted in 18 patients. In six patients the scalp sample was successful, the fetal platelet count was found to be $>50 \times 10^9$ per liter and the correct decision was made to proceed with vaginal delivery. In eight patients the sample was unsuccessful in that sufficient amounts of scalp blood for testing was not obtained or the sample was diluted by amniotic fluid and erroneously low results resulted. In these eight pregnancies a spontaneous vaginal delivery occurred before a cesarean section could be performed. All these infants had a platelet count $>50 \times 10^9$ per liter. In four infants the scalp sample produced erroneously low results that led to the wrong decision—cesarean section. In all these infants the cord platelet count was $>50 \times 10^9$ per liter.

Comment

Idiopathic thrombocytopenic purpura is an illness of young women. Some of these patients will become pregnant during an active stage of their illness. The management of the mother is simplified because the clinician can monitor the maternal platelet count and look for clinical signs of hemostatic impairment. The management of the fetus is more difficult. There is controversy within the medical community about the risk to the fetus and the type and necessity of intervention to ensure well-being. The general assumption has been that infants born to mothers with idiopathic thrombocytopenic purpura have a high risk of thrombocytopenia. Case reports that describe the occurrence of intracranial hemorrhage in these infants after delivery have led some obstetricians to recommend delivery by cesarean section in the hopes of lowering infant morbidity and mortality.[7, 8] However, the central issues are the frequency of serious morbidity in these infants and whether cesarean section could reduce the morbidity in an affected infant. The current study was performed to try to analyze predictors of neonatal thrombocytopenia.

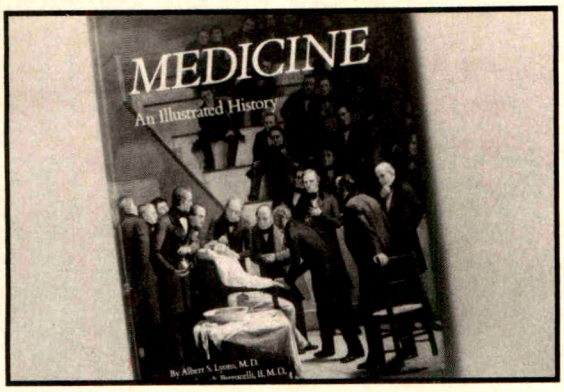
When assessing the risk for the neonate it is important to relate the results of a diagnostic maneuver or intervention to the fetal cord platelet count. The reason is that the bleeding risk at the time of delivery is related to the fetal platelet count at that time (i.e., the fetal cord sample). We previously showed that in many of these infants the platelet count continues to fall after delivery.[6] But in some reports the platelet nadir was used as the end point in the assessment of the thrombocytopenic risk. If the thrombocytopenia is most severe several days after delivery, then an excessively pessimistic estimate of the fetal risk at the time of delivery will result.

For these reasons our study focused on the neonatal cord platelet count, the measure of greatest interest to obstetricians. We found that the risk of neonatal thrombocytopenia, defined as a cord platelet count $<150 \times 10^9$ per liter was much lower than has previously been suggested and occurred in only 14.8% of our patients (95% CI, 5.9% to 23.7%). It should be noted that in many neonates the platelet count continued to fall after delivery and in some infants treatment with intravenous IgG was required. In our study, no infant bled, and only three of the 61 infants had cord platelet counts $<50 \times 10^9$ per liter at the time of delivery. One of these three infants was delivered by cesarean section for obstetric reasons and the others were vaginally delivered. No untoward event occurred in any infant.

The reason the outcome of our infants was better than that noted by other groups remains uncertain. We were careful to include every pregnant patient with idiopathic thrombocytopenic purpura who was first seen in our region to avoid a negative reporting bias. Indeed, because of the author's interest in idiopathic thrombocytopenic purpura, it is possible that we would be referred more severe cases, making it unlikely that we would underestimate the true risk. Similarly, we were careful to exclude any patients with the benign condition, incidental thrombocytopenia of pregnancy.[9] Only those patients with true idiopathic thrombocytopenic purpura and a previous history of active disease were included in the study. It is also unlikely that the relative mildness of the neonatal thrombocytopenia

that we observed was a result of maternal treatment with corticosteroids. Only 26.7% of our mothers were treated with corticosteroids and there was no difference in the proportion of the infants with thrombocytopenia in this group compared with the nontreated group.

The low frequency of thrombocytopenia in our infants and its lack of morbidity explains why none of our predelivery diagnostic or therapeutic maneuvers were shown to be useful. We did not find a correlation between the maternal platelet count and severity of infant thrombocytopenia. Neither was a history of previous maternal splenectomy more likley to be associated with infant thrombocytopenia. Corticosteroid administration did not have an obvious beneficial affect on the infants in our series, but we cannot make conclusions concerning the usefulness of corticosteroid therapy because this was not a randomized study and it is possible that the mothers with more severe disease would be more likely to receive corticosteroids. Finally, given the low frequency of thrombocytopenia overall, it would be methodologically difficult to demonstrate efficacy of corticosteroid therapy in any study. Previously, our group reported that elevated platelet associated IgG test results in the mother were predictive of neonatal thrombocytopenia,[6] and normal platelet associated IgG levels were associated with a low possibility of neonatal thrombocytopenia. In the current study, the negative predictive value of elevated platelet associated IgG remains high, but the positive predictive value has fallen concurrent with the low prevalence of neonatal thrombocytopenia.



At our center we no longer perform fetal scalp platelet sampling. In our hands the test frequently fails because of technical reasons and generates a falsely low platelet estimate, which can lead to an inappropriate intervention such as cesarean section. Other physicians also have experienced problems with fetal scalp sampling.[12-15] Although we did not perform cordocentesis, we believe it is difficult to justify this procedure for two reasons. First, it has a low, but real morbidity for mother and fetus[16] and second, as demonstrated, the likelihood of benefit being achieved is also low because the risk to the infant is low.

Our article should not be interpreted to indicate that idiopathic thrombocytopenic purpura in pregnancy does not carry any risk for neonates. However, we have found that the perinatal risk and the severity of the thrombocytopenia at the time of delivery is far lower than had previously been thought. Nonetheless, because many of these infants will have a progressive fall in platelet count after delivery they should be monitored and appropriate intervention, such as intravenous IgG or corticosteroid therapy, instituted if required.

What our study does indicate is that it is uncommon for infants to be severely affected by the maternal illness at the time of delivery. The uncommonness of a poor neonatal outcome indicates that intervention associated with maternal or fetal morbidity including cordocentesis, fetal scalp sampling, and delivery by cesarean section cannot be justified for every pregnant patient with idiopathic thrombocytopenic purpura.

MEDICINE: An Illustrated History

By Albert S. Lyons, M.D., F.A.C.S. and R. Joseph Petrucelli II, M.D.; with 14 contributors

This splendid survey will provide unending hours of pleasure. You'll enjoy relaxing with it after long hours in the office.

- brilliant color pictures review every dimension of medical history
- historical breakthroughs in medicine recorded with spellbinding prose
- timeless classic makes a splendid gift

DO YOU KNOW WHO YOUR PROBLEM PATIENTS ARE?

MONDAY, OCTOBER 9, 1990:

Tammy McDonald is 18 weeks pregnant and has an elevated AFP. She missed her perinatal exam Friday. ***Will your office call her this morning?***

Sheena Brandt's EDD was October 2nd. You haven't heard from her. ***Will your staff follow up today?***

Brenda Martin's chart was in Dr. Jessup's office. He saw her for her last exam while you were in Delivery. ***Does anyone know where her chart is now?***

You accidentally charted the wrong EDD for Nicole Arevalo. ***Will you immediately be alerted to the error?***

If your office isn't managing high-risk situations, then you're practicing high-risk medicine. Pro-active patient tracking procedures are the only sure way to protect both your patient... and your practice.

With **The OB Manager,** you can track patient progress before negative consequences result and alert your staff to critical follow through procedures. No more lost memos. No loose details. Just common sense software that retains crucial patient data and directs your staff with daily online instructions that keep you in charge.

The OB Manager's pro-active patient care program keeps you on top of your practice.

With a full range of instant reports from patient listings by provider, status, and risk factors to past due dates and abnormal test dates, **The OB Manager provides quality assurance and protection for your future.**

The New Corometrics Model 116 Intrapartum Fetal Monitor:

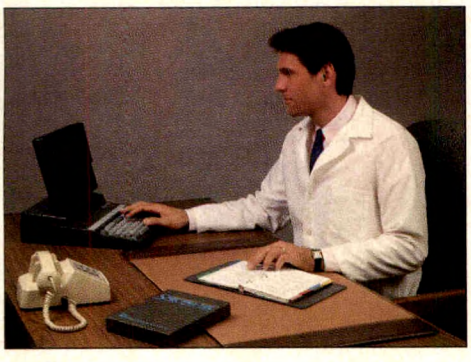
Providing Advanced Capabilities to Simplify Patient Care

Building and maintaining leadership in obstetrical instrumentation is a part of the Corometrics' tradition. And Corometrics continues to focus on patient care while answering the needs of clinicians. The Corometrics' Model 116 Intrapartum Fetal Monitor is another example of this tradition.

This advanced monitor retains all the highly successful features of the Model 115, such as autocorrelation signal processing and electronic data entry. In addition, the system offers a number of new, significant monitoring capabilities.

Dual Ultrasound Adds to Your Monitoring Capabilities

The Model 116 provides dual ultrasonic heart rate monitoring, as a standard feature, for the simultaneous, external monitoring of twins. This mode is particularly useful for monitoring twins in the early stages of labor or when performing antepartum testing. Internal/ external monitoring is also provided.



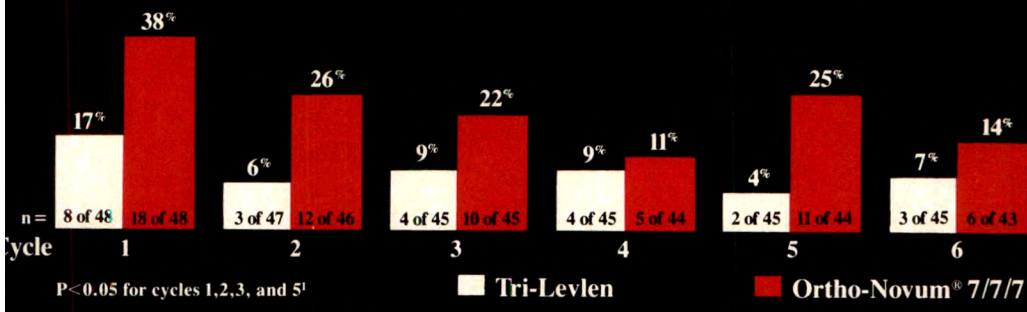
Interface With Blood Pressure Monitors For Automatic Documentation

The Model 116 accepts and automatically documents data from most widely used non-invasive blood pressure monitors, including the new Corometrics' Model 555. The measured systolic, diastolic and mean blood pressure values as well as the pulse rate are clearly recorded on the center margin of the strip chart. The Model 116 also records the time of the reading.

Beltless Tocotransducer Ensures More Complete Information

Corometrics' unique new beltless tocotransducer eliminates the instability and inconvenience associated with belted systems. A disposable adhesive baseplate holds the transducer securely in place, and the system provides reliable, useful readings even during patient position changes, sitting or walking. Patients enjoy freedom from the constrictive belt. Nurses appreciate how little attention is required to obtain a clear, continuous reading.

Data Storage and Telecommunication Improve Access to Information



Corometrics' Model 116 stores over an hour of heart rate and uterine activity data which can be transmitted via telephone lines for review or referrals. The clinician can monitor this patient data, using Corometrics' SPECTRA-TEL® software package, in the office or at another remote location.

COROMETRICS MEDICAL SYSTEMS, INC.

Tri-Levlen® means a low incidence of breakthrough bleeding/spotting*†

Multicenter study demonstrates significantly less breakthrough bleeding/spotting through the first six cycles[1]

P<0.05 for cycles 1,2,3, and 5[1]

Tri-Levlen Ortho-Novum® 7/7/7

n = number of women with a bleeding event occurring during a cycle.

TRI·LEVLEN®

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

may mean a lot to a woman

* Incidence defined as percentage of women with a bleeding event occurring at least once during a pill cycle.
Serious as well as minor side effects have been reported with the use of oral contraceptives.
The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

† Defined as intermenstrual bleeding.

TRI-LEVLEN® 28 Levonorgestrel and ethinyl estradiol
TRI-LEVLEN® 21 tablets–Triphasic regimen

BRIEF SUMMARY
Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.
The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.
CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.
MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.
RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.
ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000); the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.
PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.
2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.
3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.
4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.
5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If t patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missi period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no preci information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrog combinations to induce withdrawal bleeding should not be used as a test of pregnancy.
6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, increased risk was apparent between 6 and 12 months of use.
7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tr Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lip metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of thes findings remains to be defined.
8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertensic may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in use and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposur and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated wit the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to norm after discontinuing the drug.
9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent severe, requires discontinuation of OCs and evaluation of the cause.
10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule o pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessar since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive method Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.
11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.
12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity an quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mother receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should b deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatmen and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 yea without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed an the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs shoul stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4 OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patient with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac o renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice whil receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroi hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism whic may result in a relative pyridoxine deficiency. The clinical significance of this is yet to b determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnan woman is predisposed to the development of folate deficiency and the incidence of folat deficiency increases with increasing gestation, it is possible that if a woman become pregnant shortly after stopping OCs, she may have a greater chance of developing folat deficiency and complications attributed to this deficiency. 9. The pathologist should b advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine and liver-function tests and blood components may be affected by estrogen-containin OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling
Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.
Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.
Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."
Nursing Mothers—See "Warnings."
Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.
There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.
The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.
The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.
Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.
Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.
For full details on dosage and administration see prescribing information in package insert. 60611-1 5/86

Laparoscopic ventrosuspensions

A review of 72 cases

Ann F. E. Yoong, MB, ChB
Merseyside, England

Laparoscopic ventrosuspension is simple to perform after diagnostic laparoscopy. Serious postoperative complication is unlikely. However, patient follow-up over 6 months has not confirmed the usefulness of laparoscopic ventrosuspension in the management of deep dyspareunia or pelvic pain in association with a retroverted uterus. The success rate of laparoscopic ventrosuspension at 6 months varies from 18.6% to 46.5%. The prior use of a Hodge pessary does not predict the success of laparoscopic ventrosuspension. (AM J OBSTET GYNECOL 1990;163:1151-3.)

Key words: Laparoscopic ventrosuspension, retroverted uterus, deep dyspareunia, chronic pelvic pain, Hodge pessary

Laparoscopic ventrosuspension has been suggested as very effective in the relief of deep dyspareunia associated with retroversion of the uterus.[1] This study analyzes the incidence and outcome of laparoscopic ventrosuspensions performed at a district general hospital in the United Kingdom over a period of 5 years.

Patients and methods

The case reports of all patients who had laparoscopic ventrosuspension at Arrowe Park Hospital, Wirral, during the period from April 1982 to October 1987 were studied. The indication for the laparoscopic ventrosuspension, the previous use of a Hodge pessary, the presence of pelvic pathologic conditions, and any postoperative complications were noted.

The "success" of the laparoscopic ventrosuspension was determined by symptomatic improvement at follow-up visit 6 weeks later and at 6-month review. The review period was extended to 2 years so that further management could be observed.

Surgical technique

All laparoscopic ventrosuspensions were performed in the manner described by Steptoe and Frangenhein.[1] A laparoscope was inserted after the creation of a carbon dioxide pneumoperitoneum. The pelvis was inspected carefully and any abnormalities were noted. Skin crease incision approximately 3 cm long were made above and parallel to each inguinal ligament. A Spencer Wells forceps was then pushed into the abdomen under laparoscopic visualization and used to grasp the round ligament at its midpoint. Each round ligament was brought out of the abdominal cavity in turn. The tension on each round ligament was adjusted to obtain the correct degree of uterine anteversion and each round ligament then was plicated to the anterior rectus sheath with Dexon or nylon sutures.

Results

There were 72 laparoscopic ventrosuspensions performed in the 5 years under review. The average age of patients was 31.8 years; the majority was multiparous (Table I).

The indications for laparoscopic ventrosuspensions are shown in Table II. The primary indication for laparoscopic ventrosuspension was deep dyspareunia with chronic pelvic pain. In 43 patients (59.7%) no pelvic pathologic condition was identified at laparoscopy. Other pelfic pathologic conditions found at laparoscopy are listed in Table III.

At the 6-week follow-up 22 of the 43 patients (51.2%) in whom no pelvic condition was found stated that they felt better, 16 women (37.2%) did not feel better, and five women (27.9%) were lost to follow-up. Six months after laparoscopic ventrosuspension eight women (18.6%) reported that they felt better, 23 of the 43 (53.5%) felt they were no better, and 12 women (27.9%) failed to return (Table IV).

In 17 patients a Hodge pessary had been used to antevert the uterus before operation. These patients were listed for laparoscopic ventrosuspension only if the Hodge pessary had improved their symptoms. Table V shows that six of the 17 patients (35.3%) had improvement in their condition by laparoscopic ventrosuspension at the 6-week visit and seven of the 17

patients (41.2%) were no better. At 6-months no patient felt better, seven patients (41.2%) did not feel better, and 10 patients (58.8%) were lost to follow-up.

Two years after laparoscopic ventrosuspension, 25 of the 43 patients (58.1%) were lost to follow-up. Twelve of the 43 (27.9%) had had a hysterectomy performed. Six patients (14.0%) who had had no further surgical therapy were still under review (Table VI).

Of the 72 patients who underwent laparoscopic ventrosuspension, 64 patients were seen 6 weeks after operation and eight patients did not return for follow-up. Table VII shows that there were no postoperative complications in 39 of the 64 patients (60.9%), whereas 19 women (29.7%) experienced persistent groin pain after operation and six women had wound infection (9.4%).

Comment

This is the first study that reviews laparoscopic ventrosuspension in gynecologic practice.

Laparoscopic ventrosuspension combines diagnostic laparoscopy with a simple form of therapy. In the study by Chamberlain and Brown[2] laparoscopic ventrosuspensions were performed in 0.8% of all laparscopies, primarily at the time of diagnostic laparoscopy. Candy[8] reported on the succes of a laparoscopic ventrosuspension performed for deep dyspareunia as a result of uterine retroversion. A Hodge pessary had eliminated the patient's dyspareunia previously. At her postoperative visit the patient suffered no dyspareunia.

In this study laparoscopic ventrosuspensions were performed for chronic pelvic pain as well as deep dyspareunia. These symptoms may form part of the "pelvic pain syndrome"[4, 5] and the "chronic pelvic pain without obvious pathology."[6, 7]

In this study there were 59.7% cases in which no pelvic pathologic condition was found at laparoscopy. Gillebrand[8] reported that 63% of his patients with pelvic pain had no obvious condition at laparoscopy. Kresch et al.[9] identified 83% patients with no pelvic pathologic conditions when the pelvic pain had been in the same location for 6 or more months.

The initial improvement after laparoscopic ventrosuspension was unremarkable. Twenty-two of the 43 women (51.5%) with no obvious cause for their deep dyspareunia or pelvic pain felt better 6 weeks after the operation, whereas 16 of the 43 (37.2%) did not.

At 6 months there was a high loss to follow-up and

12 patients (27.9%) failed to return. It could be argued that those who failed to return were satisfied with their treatment; if this is assumed, 20 of the 43 patients (46.5%) were satisfied 6 months after laparoscopic ventrosuspension. Conversely, it may be argued that those who failed to returned were dissatisfied; then only eight patients (18.6%) of this group had improvement as a result of the procedure. Thus it can be seen that the success rate 6 months after laparoscopic ventrosuspension varies from 18.6% to 46.5%. The decline in patient's symptomatic improvement with time confirms Renaer's suggestion[6,7] that such patients should be followed up over a period of 1 to 2 years.

It is often stated that the success of laparoscopic ventrosuspension can be predicted from a previous trial of Hodge pessary. None of the 17 patients who had had a previously successful trial of Hodge pessary felt better at the 6-month review. However, many did not return for follow-up. If it is assumed that all 10 patients lost to follow-up at 6 months were satisfied by their treatment, then there were 10 successes among 17 patients (58.8%). If the converse is assumed, all 10 women lost to follow-up were unhappy with their treatment and no successes could be attributed to laparoscopic ventrosuspension. It is clear from this study that prior improvement with a Hodge pessary is not necessarily a good indicator of success of laparoscopic ventrosuspension.

It is interesting to note that 27.9% of these 43 patients with no obvious pelvic pathologic condition had a hysterectomy within 2 years of the laparoscopic ventrosuspension.

No serious postoperative complications occurred after laparoscopic ventrosuspension in this study. Persisting groin pain following laparoscopic ventrosuspension has been explained as a result of overtightening of the round ligaments in the course of anteversion.[10] This occurred in 29.7% of patients in this study. Urinary retention as reported by Lose and Lindholm[11] was not noted.

I thank the consultant staff at Arrowe Park Hospital for their permission to review their patients' notes.

Pregnancy-induced hypertension and acute fatty liver of pregnancy: Atypical presentations

Mark A. Brown, MD, George Passaris, MB, BS, and Mark A. Carlton, MB, BS
Sydney, Australia

Severe pregnancy-induced hypertension and markedly elevated levels of serum alkaline phosphatase developed in a 29-year-old-woman in whom one pregnancy resulted in intrauterine death. Acute fatty liver of pregnancy developed with good fetal outcome in the next pregnancy. This case suggests that pregnancy-induced hypertension and acute fatty liver of pregnancy are part of a clinical spectrum. Moreover, classic abnormalities of liver function tests need not be present in acute fatty liver of pregnancy. (AM J OBSTET GYNECOL 1990;163:1154-6.)

Key words: Pregnancy-induced hypertension, acute fatty liver of pregnancy, alkaline phosphatase

Acute fatty liver of pregnancy and pregnancy-induced hypertension (preeclampsia) may comprise the clinical ends of a single disorder. In a recent review of nine patients with acute fatty liver of pregnancy concomitant preeclampsia was found in all cases[1] and a study of liver morphology found hepatocyte fat deposits of varying degrees both in women with preeclampsia and in those with acute fatty liver of pregnancy.[2]

We describe a patient who exhibited the continuum of this spectrum across two consecutive pregnancies and whose clinical diagnosis was made difficult by the single and progressive elevation of hepatic alkaline phosphatase levels without changes in other liver enzymes.

Case report

Hypertension (blood pressure 156/90) without proteinuria at 29 weeks' gestation developed in the third pregnancy of a 29-year-old woman who had had two previous miscarriages. Fundal height was consistent with only 24 weeks' gestation, and the patient had decreasing fetal movements. Uterine ultrasonographic examination confirmed intrauterine death of a fetus of approximately 21 weeks' gestation. Initial investigations showed the following values: hemoglobin, 12 gm/dl with some red blood cell fragments and tear drop poikilocytes; platelet count, 237,000; serum creatinine, 0.07 mmol/L; uric acid, 0.40 mmol/L; bilirubin, 3 μmol/L; alkaline phosphatase, 1040 U/L (normal < 120 U/L); aspartate transaminase, 28 U/L; γ-glutamyl transferase, 19 U/L; serum albumin, 38 gm/L. Alkaline phosphatase was not fractionated and was thought at that time to represent placental infarction.

The patient was delivered vaginally of a female weighing 800 gm. Placental pathology was normal with no evidence of placental infarction or retroplacental hemorrhage.

Further investigations demonstrated a normal activated partial thromboplastin time and serum was weakly positive for antinuclear antibodies (1:160) and was negative for anticardiolipin antibodies. Blood pressure rapidly returned to normal and the patient was reviewed 2 months later when repeat antinuclear antibodies, anticardiolipin antibodies, and double-stranded binding deoxyribonucleic acid (DNA) were negative. Serum complements, immune complexes, and intravenous pyelogram were normal and creatinine clearance was 98 ml/min with no proteinuria. Urinalysis and urine microscopy were normal. Liver function test results had returned to normal with the alkaline phosphatase level at 62 U/L.

The patient returned 6 months later, 10 weeks into her fourth pregnancy with the same partner. In view of her history of three unsuccessful pregnancies she was commenced on aspirin 100 mg daily from 14 weeks' gestation and the limited data available on this therapy were explained to her. Blood pressure was 116/68; both urinalysis and physical examination were normal. Antinuclear antibodies, double-stranded binding DNA, and anticardiolipin antibodies were negative. Liver function and renal function were normal.

The patient's blood pressure remained completely

normal throughout pregnancy and at 30 weeks' gestation liver function tests were repeated in view of her past history. Her alkaline phosphatase level had risen without concomitant changes in bilirubin or other liver enzymes (Table I). Teardrop poikilocytes and macrocytosis were present on blood film with normal levels of serum B_{12} and folate. Uterine ultrasonographic examination confirmed adequate fetal growth and showed normal umbilical artery blood flow studies.

Over the ensuing 4 weeks plasma alkaline phosphatase levels rose steadily (Table I), despite cessation of aspirin. Antimitochondrial, antinuclear, and antismooth muscle antibodies were not detected, bile acid levels were normal and abdominal ultrasonographic examination showed normal liver architecture with no other abnormalities. Hepatitis B serum was negative for surface antigen and antibody, and cytomegalovirus antibodies were not detected. Electrophoresis and heat testing demonstrated the elevated level of alkaline phosphatase to consist almost totally of the hepatic isoenzyme.

An elective cesarean section was performed at 35 weeks' gestation and a healthy female weighing 2425 gm was delivered. The placenta and cord were normal histopathologically. Liver biopsy specimen obtained at cesarean section showed microvesicular fat (hematoxylin-eosin stain) in hepatocytes with some periportal sparing—features of acute fatty liver of pregnancy.

Two months postpartum the patient was completely well and liver function had returned to normal.

Comment

Whereas it has recently been suggested that pregnancy-induced hypertension and acute fatty liver of pregnancy may form a continuum of one disorder,[2] this is the first patient reported to our knowledge who demonstrates these two conditions in consecutive pregnancies. More important, the condition would not have been detected in her final pregnancy unless biochemical tests were performed, demonstrating an isolated rise in the level of alkaline phosphatase.

This patient's first pregnancy, complicated by hypertension, hyperuricemia, and abnormal liver function and resulting in intrauterine death, was consistent with a clinical diagnosis of severe pregnancy-induced hypertension. Although her next pregnancy progressed well clinically, the reemergence of elevated levels of alkaline phosphatase at 30 weeks' gestation was a worrying feature and was first presumed to reflect placental dysfunction. However, isoenzyme determination confirmed the alkaline phosphatase to be of hepatic origin despite no other abnormalities of liver function. The lack of hypertension, the normal platelet count, normal plasma urate, and lack of proteinuria meant that the increased alkaline phosphatase level was not a result of the development of pregnancy-induced hypertension in this pregnancy. To be sure that aspirin was not causing the elevated level of hepatic alkaline phosphatase, this medication was discontinued at 32 weeks' gestation but the alkaline phosphatase level continued to rise. Aspirin has been associated with the development of Reye's syndrome, with fatty vacuolization of the liver, but this disorder is generally confined to children younger than 15 years of age.

Inasmuch as elevation of alkaline phosphatase level was the only biochemical abnormality and levels of all other liver enzymes remained normal, the diagnosis of acute fatty liver of pregnancy was not made until the liver biopsy specimen was obtained at the time of cesarean section. Because the alkaline phosphatase level had been elevated in the previous pregnancy, it is possible that acute fatty liver co-existed with pregnancy-induced hypertension in that pregnancy, although the alkaline phosphatase level was not fractionated, a liver biopsy specimen was not obtained, and acute fatty liver

of pregnancy is said not to recur.[1] Therefore there was no clear-cut evidence of acute fatty liver of pregnancy in that pregnancy but there were some features that suggested that diagnosis in retrospect.

This case provides clinical support for the recent histologic proposal that pregnancy-induced hypertension and acute fatty liver of pregnancy form a continuum of one disorder.[2] More important, it demonstrates that elevations of serum bilirubin and aspartate transaminase levels need not occur for this condition to be present and the clinician should now be alert to the diagnosis of acute fatty liver of pregnancy even if the alkaline phosphatase level is the sole abnormality of liver function.

We wish to thank Dr. T. Cook, histopathologist, for his assistance with liver biopsy interpretation and Mrs. B. Smith for her assistance.

Vibroacoustic stimulation and fetal behavioral state in normal term human pregnancy

Lawrence D. Devoe, MD, Cheri Murray, RN, David Faircloth, BS, and Edgard Ramos, MD
Augusta, Georgia

Vibroacoustic stimulation may affect human fetal behavior. Continuous graphic records of simultaneous ultrasonographic observations of fetal activities and electronic fetal heart rate tracings of 30 normal term fetuses were examined visually for the occurrence of behavioral state 30 minutes before and after 3 seconds of vibroacoustic stimulation. After vibroacoustic stimulation, the total time spent in state 1 decreased significantly, that spent in state 4 increased significantly, and times spent in state 2 and indeterminate state (no state established for at least 3 minutes) were unchanged. No fetus exhibited state 3 before or after vibroacoustic stimulation. State 4 occurred in 22 fetuses after vibroacoustic stimulation with a duration of at least 30 minutes in four fetuses, and was noted in all fetuses in pre–vibroacoustic stimulation state 1 and 11 of 16 fetuses in pre–vibroacoustic stimulation state 2. Fetal heart rate accelerations occurred within 10 seconds after vibroacoustic stimulation in 94% of the fetuses studied regardless of their prior behavioral state. The variation in the onset and duration of behavioral state responses in most fetuses after vibroacoustic stimulation may depend on previous behavioral state and could be important for interpretation of antenatal assessment that uses this stimulus. (Am J Obstet Gynecol 1990;163:1156-61.)

Key words: Vibroacoustic stimulation, fetal behavioral state, fetal heart rate, fetal movement

Vibroacoustic stimulation of the human fetus by means of an artificial electronic larynx has been advocated as an adjunct to antepartum fetal assessment.[1] Vibroacoustic stimulation has been used primarily to elicit fetal heart rate (FHR) accelerations and to reduce the time required for antepartum testing; it has been shown to have predictive values comparable to those of standard nonstress testing.[2] Although the mechanisms responsible for the FHR responses that follow vibroacoustic stimulation are uncertain, studies of individual fetal biophysical activities have shown that it is primarily associated with increased baseline FHR and frequency of FHR accelerations.[3,4] However, changes in other biophysical variables, such as fetal breathing movements and body movements, have been observed, suggesting that vibroacoustic stimulation may alter the organization of fetal behavioral state.[5,6] This hypothesis has also

been supported by Lecanuet et al.[7] who applied sound stimuli of varying frequency, intensity, and repetition.

We undertook this study to evaluate the possible influence that vibroacoustic stimulation may exert on subsequent fetal behavior. We wished to determine whether normal term human fetuses capable of organized behavioral states would exhibit significant, predictable state changes after exposure to a standard vibroacoustic stimulus. We also sought to determine if a relationship existed between behavioral states that preceded and followed vibroacoustic stimulation.

Material and methods

Patient population. Thirty patients were recruited for this study from the general obstetric population at the Medical College of Georgia. All signed an informed consent and entered a study protocol approved by the Human Assurance Committee. Inclusion criteria for this investigation were as follows: (1) gestational age ≥37 and ≤42 completed weeks, (2) no evident maternal medical or obstetric complications, (3) singleton vertex presentation, without apparent anomalies and appropriate in size for gestational age, (4) intact amniotic membranes and adequate amniotic fluid volume as assessed by ultrasonographic visualization, and (5) no exposure to maternal drugs or medications other than prenatal vitamins.

Study protocol. All studies were conducted similarly between 8:30 AM and 11 PM in a quiet, darkened room. Each patient was observed approximately 2 hours after a 400 kcal breakfast, at complete rest for at least 1 hour beforehand, and positioned in a semi-Fowler position with a lateral hip displacement.

The study apparatus consisted of a standard linear array real time scanner, operating at 3.5 MHz (ADR model 4000/L, ATL Corporation, Tempe, Ariz.), an electronic FHR monitor, operating in the Doppler mode (Hewlett Packard model 8040A, Hewlett Packard Company, Andover, Mass.), an observer-operated event marker, and a specially programmed microcomputer (IBM XT, 640K RAM, IBM Corp., Boca Raton, Fla.) into which the event marker and FHR monitor were hard-wired. The software for acquiring and reconstructing the graphic display of fetal activities was developed in the Department of Biomedical Engineering at the Medical College of Georgia and has been previously described.[8] The artificial electronic larynx was a Corometrics vibroacoustic stimulator (Corometrics Corp., Wallingford, Conn.); its physical properties have been previously described[4] and it was adjusted to deliver a constant 3-second pulse. The operation of this device in free air, more than one meter removed from the maternal abdomen, was demonstrated for each patient in the hour before actual study.

Each observation session was conducted in the following manner. After the patient was admitted to the study room, no further eating or drinking was allowed. No smoking was permitted and no medications were administered. A 30-minute control period started during which simultaneous recording of FHR and entry of fetal body and breathing movements were performed. During periods when there were no observed fetal breathing or body movements, the scanning element was directed to the fetal head to verify the presence or absence of rapid eye movements. After 30 minutes of observation a 3-second vibroacoustic signal was delivered with the artificial larynx placed on the maternal abdomen, overlying the location of the fetal head. Immediately afterward a second 30-minute observation period was conducted and the same biophysical data were collected according to the same study techniques.

After the conclusion of each study the concurrent FHR and other biophysical data were recalled as a continuous graphic record and subjected to visual analysis by an independent observer. The 30-minute sequences were randomly varied for each patient so that the point at which vibroacoustic stimulation was performed was not known. The assignment of behavioral state followed a scheme, modeled after the criteria of Nijhuis et al.[9] as listed in Table I. State 1 corresponds to the "quiet sleep" state observed in the newborn; little body movement occurs, breathing patterns are regular, and the heart rate baseline shows little variability. State 2 is analogous to the rapid-eye-movement sleep state of the newborn; more body activity occurs, heart rate variability increases, and the breathing pattern becomes more irregular. State 3 may share features with the "quiet" wakeful state of the newborn; it is generally brief, rapid eye movements are present, but body movements are less frequent. State 4 is analogous to active wakefulness in the newborn; continuous body movements are present, breathing patterns are irregular, and the heart rate baseline shows marked variability with large amplitude oscillations. The assignment of behavioral state required that the defined state variables appeared together and persisted for a minimum of 3 minutes. When state criteria were not met for this length of time or were not determinable because of signal loss or failure of appropriate fetal visualization, the state was considered "indeterminate." State transitions were those epochs in which a fetus changed from one established state to another established state as characterized by the concurrent alteration of all observed state variables.

Grouped mean times spent in state and mean numbers of state transitions were calculated for the 30-minute periods before and after vibroacoustic stimulation. Only fetuses that established states during either 30-minute period were considered for final statistical

Table I. Criteria for fetal behavioral state*

State	*Fetal heart rate pattern*	*Body movements*	*Breathing movements*	*Eye movements*
1	Stable baseline; reduced variability; rare accelerations	Brief or absent	Infrequent, regular	Absent
2	Stable baseline; increased variability; accelerations episodic with movement	Episodic, gross trunkal flexion-extension	Frequent, irregular	Present
3	Wider oscillations than state 1; no accelerations	Absent	Infrequent, or absent	Present
4	Unstable, very wide oscillations; frequent episodes of tachycardia; large accelerations	Continuous, gross trunkal	Present, irregular	Present

*Adapted from Nijhuis et al.[9]

comparisons. Grouped mean parameters were compared with t tests with a p value < 0.05 considered significant. The outcome of each pregnancy was also examined for birth weight, gestational age at delivery, Apgar scores, umbilical arterial blood gas determinations, and the presence of neonatal complications.

Results

Study group. Twenty-eight of the 30 fetuses studied under this protocol had established behavioral states during the 30-minute control period or the poststimulation period and formed the basis for the statistical analysis presented in the remainder of this section. Mean (±SD) gestational age was 38.3 ± 1.2 weeks at study and 39.3 ± 1.2 weeks at delivery. Mean birth weight was 3430 ± 610 (SD) gm. No infant was below the 10th percentile in birth weight for gestational age, had 5-minute Apgar scores <7, had abnormal umbilical cord arterial blood gas values, or experienced any intrapartum or neonatal complications.

Behavioral state data. The mean duration of behavioral states of all fetuses immediately before and after vibroacoustic stimulation are shown in Fig. 1. No fetuses were observed in state 3 before or after vibroacoustic stimulation. After vibroacoustic stimulation the mean (±SD) time spent in state 1 decreased significantly from 9.7 ± 8.6 to 1.7 ± 3.5 minutes (p = 0.00004); the mean (±SD) time spent in state 2 did not change significantly (11.5 ± 10.1 vs 11.1 ± 8.4 minutes; p = 0.86); the mean (±SD) time spent in state 4 increased significantly (3.0 ± 5.4 to 11.4 ± 9.0 minutes; p = 0.00001). The mean (±SD) time spent in the indeterminate state did not change significantly (5.2 ± 5.8 vs 5.5 ± 4.8 minutes; p = 0.82). The mean (±SD) cumulative duration of time spent in any state established before vibroacoustic stimulation was 13.4 ± 9.7 minutes; the mean (±SD) persistence of all prestimulation states after vibroacoustic stimulation was 5.8 ± 6.4 minutes.

Twenty-two of the 28 fetuses had established behavioral states immediately before stimulation. Table II indicates the respective states maintained by fetuses within and after 5 minutes of vibroacoustic stimulation. During the 30 minutes after vibroacoustic stimulation, state changed in 16 of these 22 fetuses, while five of six fetuses previously in the indeterminate state established an identifiable state. Table II also shows features of behavioral state 4 after vibroacoustic stimulation. State 4 was eventually achieved by all four fetuses in state 1, 11 of the 16 fetuses in state 2, and five of the six fetuses in the indeterminate state. Both fetuses in state 4 before vibroacoustic stimulation remained in state 4. State 4 was achieved within 5 minutes by all fetuses previously in state 1, by seven of 11 fetuses previously in state 2, and by three of the five fetuses previously in the indeterminate state. The duration of post–vibroacoustic stimulation state 4 varied from 4 to 30 minutes for fetuses previously in states 1 and 2 and from 5 to 19 minutes for those previously in indeterminate states. However, mean durations of post–vibroacoustic stimulation state 4 were similar among fetuses previously in states 1 or 2. State 4 persisted in four fetuses for virtually the entire post–vibroacoustic stimulation period and was still present at the end of the 30-minute observation period for the three fetuses not in state 4 before vibroacoustic stimulation. State 4 was never achieved by five fetuses in pre–vibroacoustic stimulation state 2 and one fetus with pre–vibroacoustic stimulation indeterminate state.

The mean (±SD) numbers of state transitions before vibroacoustic stimulation (1.2 ± 0.94) and after vibroacoustic stimulation (1.5 ± 0.94) were not significantly different (p = 0.25). A maximum of three state transitions was observed either before or after vibroa-

*Mean ± SD.

coustic stimulation. Within 10 seconds after vibroacoustic stimulation, 26 of 28 fetuses exhibited FHR accelerations in excess of 15 beats/min in amplitude and 15 seconds' duration; FHR accelerations were absent in one fetus in prestimulus state 2 and one fetus in the indeterminate state.

Comment

This study attempted to determine, under controlled environmental conditions and observation techniques, whether patterns of organized fetal behavior are changed after a brief vibroacoustic stimulus. Interest in the possible behavioral effects associated with vibroacoustic stimulation has been provoked by its application in the assessment of both antepartum[1] and intrapartum[10] fetal well-being, and the current uncertainties about its mechanism of action.

We observed apparent alterations in fetal behavioral state after the application of vibroacoustic stimulation, as shown by times spent in state and the nature of the

behavioral state achieved. In contrast with the previous studies of Gagnon et al.[3, 5] and our own group[4, 6] that examined individual behavioral variables, this study attempted to view integrated, concurrent changes in the variables that describe organized fetal behavior. Although rapid eye movements were not continuously tracked throughout each study, the previous data of Nijhius et al.[9] suggest that the coincidence of other state variables (e.g., FHR pattern, fetal body movements, and breathing patterns) are predictive of organized state in over 70% of observed epochs when gestational age is beyond 37 weeks, as was the case in all of our studies. Therefore as a qualification of our observations it is possible that coincidental cycles of fetal motility rather than "true" states might have been present in some instances when state 2 was assigned. Because of the characteristic concurrent patterns of fetal activity and FHR baseline associated with state 4, it is less likely that errors occurred in the identification of this state. Our data suggest that the fetal state established before vibroacoustic stimulation may influence the nature and duration of subsequent fetal states. Fetuses with a pre–vibroacoustic stimulation state 1 consistently and rapidly converted to a post–vibroacoustic stimulation state 4; fetuses with a pre–vibroacoustic stimulation state 4 maintained their behavior patterns. Most (57%) of our study fetuses were in state 2 before vibroacoustic stimulation, a finding consistent with that reported by Martin[11] for normal fetuses of this gestational age. The behavioral responses of fetuses in state 2 after vibroacoustic stimulation appear less consistent and one third of this group never established state 4 after vibroacoustic stimulation. These responses are consistent with those reported by Lecanuet et al.[7] despite the differences in the stimuli used in their study.

In view of our findings, the previous concept that fetal state may be "disorganized" by vibroacoustic stimulation[5] should probably be reconsidered and replaced by the concept that, under some circumstances, fetal behavioral state may be "reorganized" via evoked state transitions. The marked variability in poststimulus behavior for those fetuses not in states 1 or 4 suggest that the mechanism for FHR accelerative responses to this stimulus is not simply caused by state conversion. FHR accelerations may be observed in all states except state 3 and therefore their spontaneous occurrence does not require a change of state.[9] Because most study fetuses showed a brief tachycardiac response to vibroacoustic stimulation, regardless of the ultimate onset and duration of poststimulus state, the mechanism for this brief response may be independent of behavioral state or the function of higher cortical centers.[12] Alternately, it is possible that variations in vibroacoustic stimulation response may reflect variations in the intrauterine intensity of the stimulus, as demonstrated by Gerhardt et al.[13]

Our findings also have implications for clinical fetal assessment that may involve the adjunctive use of vibroacoustic stimulation. First, the apparent relationship between preexisting fetal state and subsequent vibroacoustic stimulation response suggests that the most immediate and dramatic poststimulus effects occur if the fetus has been previously in state 1. Second, most fetuses undergoing testing after 37 weeks are in state 2 before vibroacoustic stimulation and their subsequent behavioral responses are the least predictable. Third, a transient "response" in any individual behavioral variable, such as FHR baseline, after vibroacoustic stimulation should not imply that higher cortical centers of the fetus are intact. This does not invalidate the use of either the "fetal acoustic stimulation test"[1] or the more conventional nonstress test for assessing fetal condition. It simply suggests that the observation of FHR accelerations alone does not constitute a comprehensive statement of fetal condition. Finally, it is not clear that sustained episodes of any behavioral state, especially state 4, are of any consequence to fetal well-being; however, they may be important for the subsequent application and interpretation of other testing methods. It would seem prudent to infer from our experience that such sustained responses are not rare, may exceed 30 minutes, and should probably be considered if further antepartum biophysical testing immediately follows the use of vibroacoustic stimulation.

Successful conservative management of primary nonmetastatic cervical choriocarcinoma

Avraham Ben-Chetrit, MD,[a] Simcha Yagel, MD,[a] Ilana Ariel, MD,[b] David Zacut, MD,[a] Shlomo Shimonovitz, MD,[a] and Drorit Celnikier-Hochner, MD[a]

Jerusalem, Israel

Primary cervical choriocarcinoma is a rare disease; since 1915 only about 60 cases have been published. The case presented here can be defined as primary cervical choriocarcinoma since it fulfills all the criteria delineated previously. (Am J Obstet Gynecol 1990;163:1161-3.)

Key words: Cervical choriocarcinoma, hysterectomy, chemotherapy

Primary cervical choriocarcinoma is an extremely rare disease. This condition can be easily misdiagnosed as other, more common cervical pathologic conditions such as threatened abortion, benign or malignant lesions of the cervix, and even cervical pregnancy. Saito et al.[1] defined the criteria of ectopic choriocarcinoma as follows: (1) There is no primary focus of choriocarcinoma in the uterine corpus. (2) The histopathologic diagnosis should be confirmed as choriocarcinoma. (3) Extrauterine mole or normal intrauterine pregnancy should be excluded. (4) Intramural choriocarcinoma in the uterine corpus should not be considered as ectopic choriocarcinoma. According to the current literature the most common treatment is a combination of abdominal hysterectomy and chemotherapy. We present a case of primary cervical choriocarcinoma in a relatively young patient who desired to preserve her fertility; the disease was successfully treated by local excision of the lesion followed by chemotherapy.

Case report

A 33-year-old, healthy, Jewish woman, married with three children, had three uneventful term pregnancies. Her last pregnancy was terminated 1 year before her present admission. She used an intrauterine contraceptive device and reported regular menses until 1 month before her admission when she noted irregular vaginal bleeding not related to coitus. On examination in another hospital the uterus was normal with no palpable adnexal masses. The intrauterine contraceptive device was removed. A 0.5 cm flat cervical lesion was found, and a biopsy was performed. Histologic examination was interpreted as a well to moderately differentiated invasive squamous cell carcinoma of the cervix. A month later the patient came to our hospital for second opinion and treatment. On admission, general physical examination gave normal findings. Pelvic examination showed a 0.5 × 1 cm cervical lesion. The uterus was normal with no palpable adnexal masses. Laboratory findings including peripheral blood count, platelet count, SMA-C test, erythrocyte sedimentation rate, creatinine clearance, and the markers carcinoembryonic antigen, α-fetoprotein, and CA 125 were within normal limits. The β-subunit human chorionic gonadotropin (β-hCG) level was 32 U (normal value, <10 U). Chest x-ray film was normal.

The patient underwent conization to determine the extent of the disease; the cone biopsy specimen measured 3 cm in diameter and had an irregular surface. The entire specimen was sectioned and examined mi-

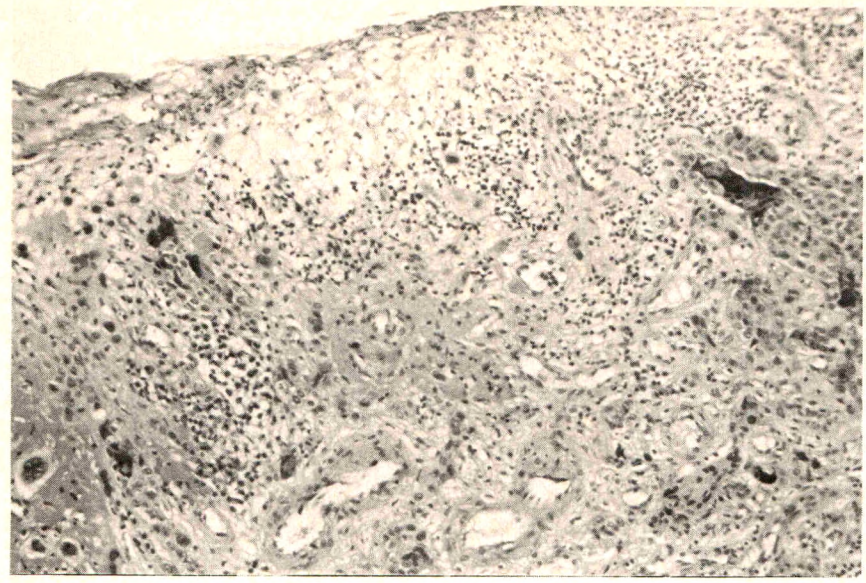

Fig. 1. Choriocarcinoma of uterine cervix. Overlying mucosa is ulcerated. (Hematoxylin and eoxin. ×110.)

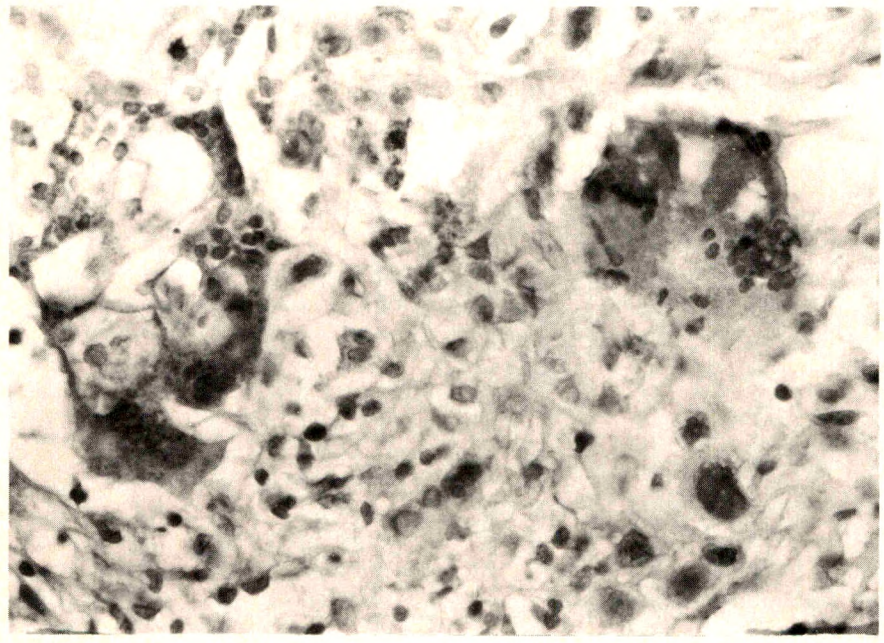

Fig. 2. β-hCG is demonstrated in syncytiotrophoblasts by immunoperoxidase technique. (×440.)

croscopically (Fig. 1). Tumor was found in the submucosa of the transformation zone between 12 and 3 o'clock. It consisted of masses of large mononuclear cells adjacent to groups of multinucleated cells and intermingled with blood lakes. A diagnosis of choriocarcinoma was made. The syncytiotrophoblasts stained positively for β-hCG by the immunoperoxidase technique (Fig. 2). Lines of resection were free of tumor. Reexamination of the previous biopsy specimen showed the same picture. Five days after the conization, serum β-hCG levels were <10 U; serum α-subunit human chorionic gonadotropin determination was not available in our hospital at that time. Further metastatic workup including brain and chest computed tomographic scan gave normal results. As the patient was interested in preserving her fertility, laparoscopy was performed and macroscopic lesions in the pelvis were excluded. Ten milliliters of clear fluid aspirated from the pouch of Douglas contained no malignant cells. Fractionated curettage showed a normal endocervix

and no evidence of trophoblastic disease. As conservative treatment has been adopted, the patient received two courses of intravenous methotrexate and folinic acid. Each course lasted 8 days and included four doses of 1 mg/kg methotrexate every other day and 0.1 mg/kg folinic acid on the alternating day, with a week's interval between the two courses. During and after the completion of the treatment the serum β-hCG levels, peripheral blood all count, and SMA-C test results were within normal limits. A repeated chest x-ray film did not show any evidence of metastasis.

A year after treatment, the patient's condition is good. Results of pelvic examination are normal, and β-hCG levels are <10 U/ml.

Comment

Our case was originally interpreted as a squamous cell carcinoma of the cervix. The latter occurs in the cervix with much greater frequency than choriocarcinoma. The cells of squamous carcinoma may have abundant eosinophilic cytoplasm as seen in cytotrophoblasts and may have more than one nucleus, thus resembling syncytiotrophoblast. It is not surprising therefore that a similar misdiagnosis has been described in another case by Tsukamoto et al.[2] The diagnosis of choriocarcinoma of the cervix should be confirmed by immunoperoxidase staining for β-hCG, as in our case.

Hysterectomy followed by chemotherapy is the treatment described in all the cases reported in the literature. In view that our patient wished to preserve her fertility and that the treatment for uterine choriocarcinoma during reproductive age may involve chemotherapy only, we decided to consider a conservative management. The negative metastatic workup supported our management.

In our opinion a nonmetastatic, primary cervical choriocarcinoma that occurs in a young patient who desires to preserve her fertility can be treated by local resection of the tumor followed by chemotherapy.

The prognostic significance of CA 125 half-life in patients with ovarian cancer who have received primary chemotherapy after surgical cytoreduction

Verda J. Hunter, MD, Lee Daly, PA-C, Michael Helms, PhD, John T. Soper, MD, Andrew Berchuck, MD, Daniel L. Clarke-Pearson, MD, and Robert C. Bast, Jr., MD
Durham, North Carolina

Fifty-four patients with advanced epithelial ovarian cancer were monitored with serial serum CA 125 levels after surgical cytoreduction and during multi-agent chemotherapy with cisplatin-containing regimens. CA 125 half-life of <20 days was associated with prolonged overall survival ($p < 0.015$). In those patients who eventually were found to be disease-free at surgical surveillance procedures, normalization of serum CA 125 levels to <35 U/ml within 65 days of primary operation also suggested an improved survival ($p < 0.059$). (AM J OBSTET GYNECOL 1990;163:1164-7.)

Key words: CA 125 half-life, ovarian cancer, prognosis

Serum CA 125 levels have been shown to correlate with response to therapy in patients with ovarian cancer.[1-3] Rapid and complete regression of tumor should be associated with a rapid decline in levels of the serum marker and might correlate with a favorable prognosis. In a report by van der Burg et al.,[4] patients with a CA 125 half-life of 20 days or more had a 3.2-fold higher progression rate and shorter median time to progression than did patients with a CA 125 half-life during the first month after chemotherapy correlated with progression-free survival. In an attempt to confirm and extend these potentially important observations, CA 125 half-life was calculated in patients with advanced stage epithelial ovarian cancer who had received primary chemotherapy after surgical cytoreduction.

Material and methods

Serial CA 125 levels were studied in 54 women with ovarian cancer who had undergone surgical cytoreduction followed by multi-agent chemotherapy at Duke University Medical Center between March 1984 and January 1989. Patients ranged in age from 25 to 86 years with a median of 57 years. Forty-four women had stage III disease and 10 had stage IV disease. All had epithelial tumors: 50 serous, one mucinous, and three undifferentiated carcinomas.

All patients underwent surgical cytoreduction at the time of initial diagnosis. Sixteen patients had tumor nodules <1 cm after surgery and 31 had nodules >1 cm. In seven patients who had received initial operation elsewhere, the precise status of residual disease was unknown. All patients received cisplatin-containing multi-agent chemotherapy at 3- to 4-week intervals according to Gynecologic Oncology Group protocols. Twenty-nine patients each received seven to nine cycles of cyclophosphamide (500 mg/m²) with cisplatin (50 mg/m²). Twenty patients received cyclophosphamide (500 mg/m²), cisplatin (50 mg/m²), and doxorubicin (50 mg/m²) for eight cycles. In six of these cases bacillus Calmette-Guérin was added to the regimen. Four patients received cyclophosphamide (1000 mg/m²) and cisplatin (100 mg/m²) during each of four cycles and one patient underwent six cycles of intraperitoneal cisplatin and intravenous cyclophosphamide chemotherapy.

Initial serum samples were obtained from 28 patients before cytoreductive operations, from 15 patients before the initiation of chemotherapy, and from 11 patients before the second course of chemotherapy. All patients were followed up with serial CA 125 value determinations and second samples were obtained in all cases within 90 days of operation. All sera were promptly separated and frozen at −70° C. Serum CA 125 was assayed according to directions in kits obtained from Centocor (Malvern, Pa.) as previously described.[1] All 54 patients initially had elevated CA 125 (>35 U/ml).

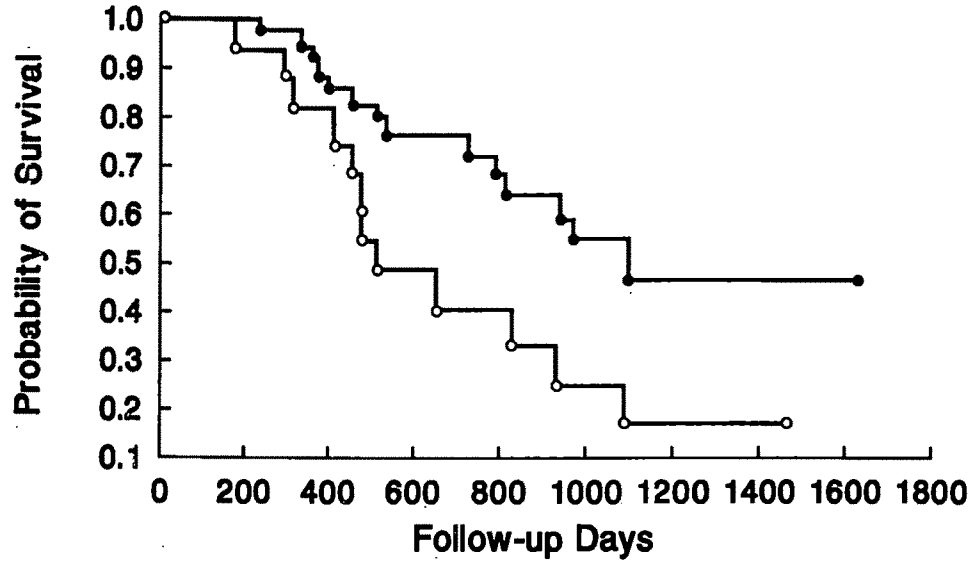

Fig. 1. Probability of survival for patients with ovarian cancer with serum CA 125 levels ≤20 U/ml *(solid circles)* and >20 U/ml *(open circles)*.

Days of follow-up were calculated from the date of operation to either the date of death or the date of last examination. CA 125 half-life for individual cases was calculated with the formula described by van der Burg et al.[4]:

$$T_{1/2} = \frac{dT}{\text{Log}_2\,(\text{CA 125-1}/\text{CA 125-2})}$$

where CA 125-1 is the prechemotherapy or preoperative value, CA 125-2 is the first normal CA 125 value or the lowest CA 125 value, if CA 125 did not normalize between 3 months after the start of therapy, and dT is the time between CA 125-1 and CA 125-2.

Patients were grouped as having CA 125 half-life values less than or more than different values. The interval to normalization of CA 125 (<35 U/ml) was also calculated for each patient. The date of progression was defined as the first date on which progressive, persistent, or recurrent tumor growth could be detected by clinical, radiologic, or surgical examination.[5] Second-look laparoscopies or laparotomies were performed in 39 patients. Four patients refused operation and 11 patients experienced progression before an operation could be performed. Median follow-up for all patients was 606 days and minimum follow-up was 305 days.

Survival curves were calculated and the resulting plots displayed through Kaplan-Meier analysis.[6] Tests of differences between the curves were made with the log-rank test. The test statistic consisted of a χ^2 with the degrees of freedom being one less than the number of curves being considered.

Results

Survival for 38 patients with serum CA 125 half-life values ≤20 days was compared with that for 16 patients with CA 125 half-life >20 days (Fig. 1). Overall survival was significantly greater in patients with a CA 125 half-life ≤20 days ($p < 0.015$, two-tailed). Median survival was approximately twofold greater in those individuals with the shorter CA 125 half-life. The correlation between half-life of serum CA 125 and time to disease progression did not achieve statistical significance ($p < 0.13$, two-tailed).

When all patients were considered, the interval required for CA 125 to fall below 35 U/ml did not correlate with disease-free or overall survival. However, if the 39 patients who underwent second-look surgical surveillance procedures were divided into subsets with and without residual ovarian cancer, an interesting trend was observed for those patients who were disease-free at second look (Fig. 2). In this group eight individuals whose serum CA 125 value normalized by 65 days after initial operation appeared to have improved survival when compared with five patients whose CA 125 level had not normalized. The number of patients in each group was, however, quite small and the differences only approached statistical significance ($p < 0.059$, two-tailed). The interval to normalization of CA 125 did not correlate with survival in those individuals with positive surgical surveillance procedures.

Comment

Lavin et al.[7] found that a failure to normalize CA 125 levels after 3 months of treatment was consistently as-

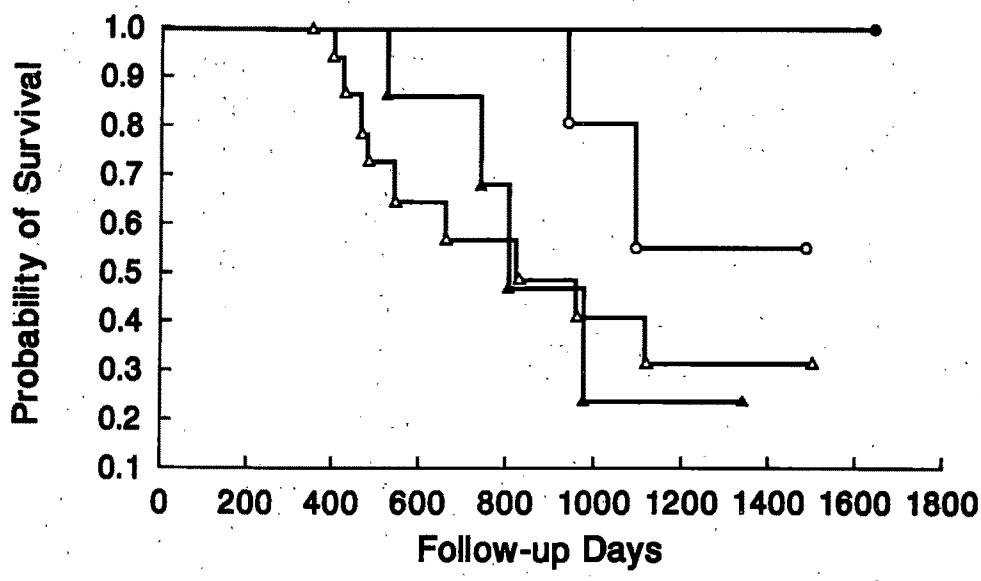

Fig. 2. Probability of survival for patients with ovarian cancer with positive *(triangles)* or negative *(circles)* surgical surveillance procedures. *Solid figures* indicate a fall in CA 125 level to >35 U/ml by 65 days.

sociated with persistence of ovarian cancer at completion of chemotherapy. All patients with negative surgical surveillance procedures had experienced a decline of CA 125 levels to <35 U/ml by 3 months. Consequently, the CA 125 level 3 months after treatment appeared to predict response to therapy in epithelial ovarian cancer. Van der Burg et al.[4] extended these observations, correlating the half-life of CA 125 with the rate of disease progression and the time to disease progression. In patients with a CA 125 half-life >20 days, a median time to disease progression of 11 months was found compared with 43 months for patients with half-life <20 days. The physiologic half-life of CA 125 has been estimated to be 4.8 days.[8] Larger values are thought to reflect the continued production of CA 125 by residual tumor. Rustin et al.[5] observed that disease-free survival was improved in those patients whose serum CA 125 had fallen sevenfold by 35 days after the initiation of chemotherapy.

This report extends these earlier studies to consider overall survival. Our experience in 54 patients with advanced ovarian cancer who had undergone surgical cytoreduction followed by multiagent cisplatin-based chemotherapy supports the observation that CA 125 half-life is a potentially important prognostic variable. Patients with a short CA 125 half-life had an improved overall survival when compared with patients with a CA 125 half-life >20 days.

However, a statistically significant correlation was not observed between CA 125 half-life and disease-free survival, in contrast to observations of van der Burg et al.[4] Our study population was still relatively small and statistical significance might have been achieved if a larger number of patients could have been studied. Our study was restricted to patients with stage III and IV disease, whereas the previous report[4] included patients with early stages of tumor spread. In early-stage disease surgical removal of tumor would provide complete cytoreduction and eliminate the major source of antigen before chemotherapy. In such patients a short half-life would be observed related to the operation rather than to the chemotherapy. Patients with early stage disease should also have the best prognosis and the longest time to tumor progression. The criteria used to determine disease progression constitute another difference between the two studies. Our use of positive surgical surveillance procedures to determine the date of disease progression may have minimized differences in disease-free interval between groups with rapid and slow CA 125 half-lives. In the earlier study by van der Burg et al.,[4] it was not stated how often surgical surveillance procedures had been performed or whether surgical findings had been used to determine the date of disease progression. Finally, patients may have been followed up at more frequent intervals after chemotherapy in the study by van der Burg et al., permitting a more precise determination of the date of clinical progression.

In our study a trend was observed toward correlation of survival with normalization of CA 125 by 65 days, but only in the subset of patients who had negative second-look surgical surveillance procedures. Lack of prognostic significance in the presence of persistent tumor may simply reflect the substantial importance of

macroscopic tumor at second look in determination of subsequent survival. A rapid fall in serum CA 125 levels need not preclude the presence of residual disease at second look. If tumors contained a small but significant fraction of drug-resistant cells, a majority of sensitive cells could be eliminated rapidly and still leave residual disease. Alternatively, rapidly proliferating cells might be quite sensitive to cytotoxic chemotherapy, but a small fraction of surviving cells regrow at a similarly rapid rate.

With cisplatin-based regimens a substantial fraction of patients will have disease recurrence within 2 years after a negative second-look procedure. However, the remainder will survive disease-free. In those patients with negative surgical surveillance procedures, the accurate identification of a subset who are destined to have disease recurrence would be of value in planning trials of more aggressive consolidation therapy. High-dose alkylator therapy with autologous bone marrow transplantation, for example, is likely to be most effective against minimal residual disease but is associated with significant morbidity and mortality.[9] A reliable correlate of poor prognosis in patients with a negative second-look operation would aid in selection of appropriate criteria for bone marrow transplantation or similarly aggressive consolidation chemotherapy.

Correlation of CA 125 half-life during primary therapy with subsequent overall survival is consistent with the importance of a response to the initial cytotoxic regimen and to a general lack of effective second-line therapy. Rate of response to primary chemotherapy has been correlated with the subsequent course of disease in leukemia, lymphoma, testicular carcinoma, and gestational trophoblastic neoplasia. On the basis of this report and from previous studies,[4, 5] this principle is likely to extend to epithelial ovarian carcinoma.

Management and outcomes of pregnancies complicated by human B19 parvovirus infection: A prospective study

John F. Rodis, MD, Dorothy L. Quinn, MS, G. William Gary, Jr., MPH, DrPH, Larry J. Anderson, MD, Sally Rosengren, MD, Matthew L. Cartter, MD, Winston A. Campbell, MD, and Anthony M. Vintzileos, MD

Farmington and Hartford, Connecticut, and Atlanta, Georgia

During a large statewide outbreak of fifth disease in Connecticut in 1988, 39 pregnant women were identified who had serologic evidence of recent human B19 parvovirus infection. The patients were followed up prospectively with targeted fetal ultrasonographic examinations to detect signs of fetal hydrops. Of these 39 pregnant women, 37 had healthy infants and two patients had miscarriages. None of the fetuses developed hydrops. We propose that pregnant women exposed to B19 parvovirus be tested for evidence of IgG and IgM B19-specific antibodies and that targeted fetal ultrasonography be considered when IgM antibodies are found. Percutaneous umbilical blood sampling and intrauterine transfusion can be considered in cases of B19 parvovirus-associated hydrops and anemia. The overall fetal loss rate in this prospective follow-up group was 5%. (AM J OBSTET GYNECOL 1990;163:1168-71.)

Key words: Parvovirus infection in pregnancy, targeted ultrasonography, hydrops

Intrauterine infection with human B19 parvovirus has been associated with fetal hydrops and death,[1-7] although the outcomes have been normal in the majority of cases. During a large and widely publicized statewide outbreak of erythema infectiosum (fifth disease), the childhood exanthem caused by B19 parvovirus, many pregnant women were exposed to the virus. More than 1000 pregnant women had blood tests for the presence of IgG and IgM parvovirus-specific antibodies. This article pertains to the pregnant women who were identified as having evidence of recent B19 parvovirus infection (i.e., B19 IgM-antibody–positive). The purpose of this report is to define the fetal risks associated with maternal B19 parvovirus infection during pregnancy in a prospective follow-up population and to propose a management protocol for pregnancies complicated by B19 parvovirus infection.

Material and methods

During a large statewide outbreak of erythema infectiosum from December 1987 through December 1988, many pregnant women contacted their physicians or the Connecticut Pregnancy Information Service at the University of Connecticut Health Center. Most of the women had either direct or indirect contact with a child with erythema infectiosum; many worked in schools with erythema infectiosum outbreaks. Patients were advised to have their blood tested for the presence of IgG and IgM parvovirus-specific antibodies. Testing was performed at the Centers for Disease Control by a previously described[8] enzyme-linked immunosorbent assay method.

Women with serologic evidence of recent infection by B19 parvovirus (i.e., B19 parvovirus IgM-antibody–positive) were advised to undergo targeted fetal ultrasonographic examinations, with special attention given to signs of fetal hydrops (polyhydramnios, placentomegaly, pericardial or pleural effusions, ascites, skin or scalp edema). Ultrasonographic examinations were performed at 1- to 2-week intervals until at least 6 to 8 weeks had elapsed from the date of maternal exposure, when it was known. In cases in which the timing of B19 parvovirus exposure was ill defined, ultrasonography was performed for 6 weeks from the time the B19 parvovirus IgM antibody–positive serum was drawn. This report includes only those patients whose pregnancies were uneventful at the time of serologic testing. In other words, to avoid selection bias, patients who had miscarriages who were then sent for B19 parvovirus testing are not included. Ultrasonography was performed by the Maternal-Fetal Medicine faculty of the University of Connecticut Health Center.

Pregnancy outcomes were obtained in all cases; in-

formation was obtained by the referring physicians or the pediatricians who had examined the newborns. Information obtained included birth weights, Apgar scores, gestational age at delivery, and documentation of major or minor congenital anomalies. In cases of spontaneous abortion fetal and placental tissues were examined histologically.

Results

During the study period 39 pregnant women were identified who had recent evidence of B19 parvovirus infection, all of whom were followed prospectively with fetal ultrasonographic examination. Pregnancy outcomes were available for all women. Thirty-seven (95%) were delivered of healthy newborns, 36 at term and one patient delivered of twins at 35 weeks. None of these fetuses had signs of fetal hydrops. One of the 38 infants had mild hypospadias. Two patients had spontaneous abortions for an overall pregnancy loss rate of 5%.

With regard to the two losses, one occurred in a patient with infertility who had suboptimal rises in quantitative β-human chorionic gonadotropin before her exposure to a child with erythema infectiosum early in the first trimester. She subsequently had falling β-human chorionic gonadotropin values and never required a dilation and curettage; thus no tissue was available for histologic examination. The other spontaneous abortion occurred in a woman exposed to B19 parvovirus at 10 weeks' gestation. Fetal heart tones were auscultated and serum was tested for B19 parvovirus antibodies. Two weeks later the patient had a spontaneous abortion. Histologic examination of the placenta revealed severe erythroblastosis. Because of formalin fixation of the products of conception, B19 parvovirus deoxyribunucleic acid probes could not be used to identify viral deoxyribonucleic acid.

Table I shows the gestational age at the time of serologic testing in the 39 women.

Table I. Distribution of gestational ages at time of serologic testing

Gestational age (wk)	*No.*	*% of total*
≤5	2	5.1
7-12	10	25.6
13-18	11	28.2
19-24	5	12.8
25-30	6	15.4
31-36	2	5.1
≥37	3	7.7
TOTAL	39	99.9

Comment

In most cases of maternal B19 parvovirus infection the fetus is not adversely affected, whereas in others—for reasons not well understood—miscarriages, fetal hydrops, and death may occur. The actual incidence of fetal death after maternal infection is not well established because previous studies have been retrospective and subject to selection bias. A retrospective review of all cases reported in the literature suggested a fetal loss rate of 38%,[4] whereas a recent report from West Germany found a 26% rate of hydrops in 39 pregnant women.[9] However, an unpublished prospective study from the United Kingdom suggests that the B19 parvovirus–associated fetal death rate after maternal infection is <10%.[10] To the best of our knowledge this study represents the first published report of a prospectively followed cohort of pregnant women with recent B19 parvovirus infection. Our overall 5% fetal loss rate is consistent with the findings of the unpublished British study.

If B19 parvovirus infection is considered from the larger public health prospective, three factors determine the risk of adverse pregnancy outcome. First is the overall susceptibility rate in the population. Previous studies have suggested that approximately 50% of adults in the United States have serologic evidence of past B19 parvovirus infection and are thus immune. During the period of our study 53% of pregnant women tested had evidence of past infection (M. L. C., unpublished data, 1988). The second factor to be considered is the actual rate of infection in these susceptible individuals in the setting of a community outbreak of erythema infectiosum. Previous epidemiologic studies would suggest that approximately 50% of susceptible household contacts become infected.[6] Data from one Connecticut community that was extensively studied by the Centers for Disease Control during the 1988 outbreak revealed that 19% of susceptible adult school personnel became infected in schools with erythema infectiosum outbreaks.[11] The third factor in the fetal risk equation is the actual B19 parvovirus–associated fetal loss rate in cases of maternal infection. Although two pregnancy losses occurred in 39 women (5%) in our study, one of these losses most likely was not related to B19 parvovirus infection, and therefore the B19 parvovirus–associated fetal loss rate may be as low as 2.5%

Approximately 50% of adults lack immunity to B19 parvovirus infection; as many as 20% of susceptible adults become infected after exposure in a school setting and 2.5% to 5% of these may have adverse pregnancy outcome once they become infected. Thus the overall B19 parvovirus–related fetal loss rate for pregnant women whose immunologic status is unknown was approximately 2.5 to 5/1000 pregnant women. As noted, we did not include patients who were tested after miscarriage in an effort to avoid selection bias. Thus there could have been other B19 parvovirus–related

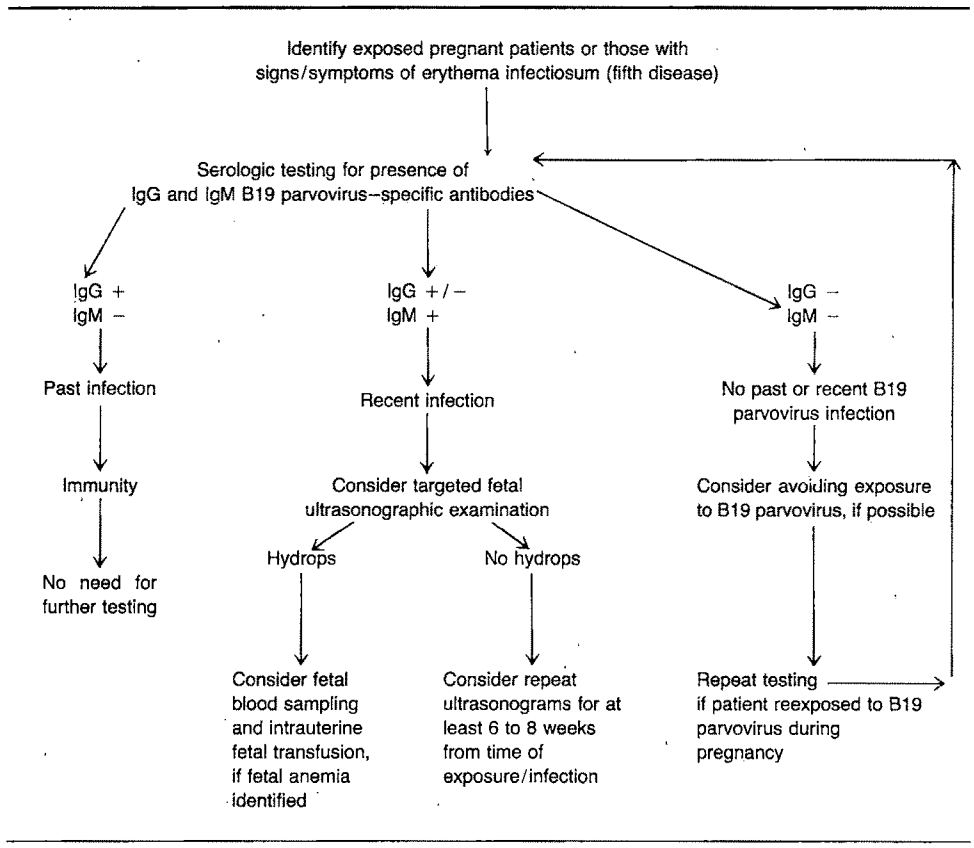

Fig. 1. Management protocol for B19 parvovirus exposure in pregnancy.

first-trimester losses. However, during the study period there were very few such cases. Therefore it is unlikely that their inclusion would have significantly altered the cited risks. Moreover, in keeping with the prospective nature of our study, we thought that these cases would best be excluded. Currently, serologic testing for B19 parvovirus infection is not widely available. The Centers for Disease Control and some state health departments offer B19 parvovirus antibody testing on a limited basis that includes testing pregnant women with exposure to B19 parvovirus or symptomatic B19 parvovirus infection.

We have previously suggested[4] that since the cause of fetal death in most cases appears to be profound fetal anemia, intrauterine transfusion might be a potential therapy in affected fetuses. Recently Schwarz et al.[9] reported intrauterine fetal blood transfusion in three affected fetuses with successful outcomes in all cases. This treatment has not been tested in a controlled study and thus is not recommended for routine treatment of B19 parvovirus–related fetal hydrops.[12]

We propose the management protocol depicted in Fig. 1. Pregnant women exposed to B19 parvovirus infection can be tested for B19 parvovirus antibodies. In general, maternal IgM antibodies appear 3 to 4 days after the onset of clinical illness, whereas IgG antibodies appear within 7 days. The IgM antibodies persist for 3 to 4 months and the IgG antibodies persist for years.[6-12] Therefore those who are positive for IgG antibodies and negative for IgM antibodies can be assured that they are at little, if any, risk from B19 parvovirus infection. Those with IgM antibodies have recently been infected and their fetus may be at risk of B19 parvovirus–related fetal death. The possibility of a B19 parvovirus adverse effect on the fetus can be monitored by directed ultrasonography and signs of hydrops including skin or scalp edema, ascites, hepatomegaly, placentamegaly, pleural or pericardial effusion, or altered fetal biophysical activities (e.g., decreased fetal movement) suggest that the fetus may be adversely affected by the infection. Percutaneous umbilical blood sampling can be considered to clarify the diagnosis by looking for severe anemia and evidence of B19 parvovirus infection. Fetal infection can be documented by demonstrating B19 parvovirus antigens or deoxyribonucleic acid and is strongly suggested by demonstrating eosinophilic inclusions and marginated chromatin characteristic of B19 parvovirus–infected erythroid precursors. Intrauterine blood transfusions can be considered to treat the affected fetus, although

its role in the treatment of this condition is yet to be defined and needs further study. Treatment with immune globulin is another therapeutic modality that merits study.

The fetus with a normal ultrasonogram on initial examination may develop abnormalities later; therefore consideration should be given to following the fetus with additional ultrasonograms. The timing of ultrasonically detectable hydrops in relationship to maternal infection and fetal death is not well understood; it is known, however, that fetal death usually occurs between 4 and 6 weeks but has occurred up to 12 weeks after symptomatic infection in the mother. The role of ultrasonography in follow-up of these pregnancies is not well defined and requires further study. Some authors[13, 14] have suggested that maternal serum α-fetoprotein levels be monitored because elevated values may identify the adversely affected fetus. One disadvantage of this approach is the many other causes of elevated maternal serum α-fetoprotein levels. Moreover, because the maternal serum α-fetoprotein test is primarily performed between 15 and 18 weeks' gestation, its value would be limited to cases of maternal infection during the late first or early second trimester.

Women susceptible to B19 parvovirus infection (IgG and IgM negative) should be advised of the risks of continued exposure to their fetus, and any decision to attempt to decrease this risk should be made by the women after consulting with other involved persons such as family members, employers, and public health officials.[12]

In conclusion, pregnant women with known B19 parvovirus exposure or signs or symptoms of fifth disease should be tested for presence of IgG and IgM parvovirus-specific antibodies. In patients with serologic evidence of recent infection (IgM positive), targeted ultrasonographic examinations and maternal serum α-fetoprotein testing may be helpful in identifying affected fetuses. It would appear that the fetal loss rate after maternal B19 parvovirus infection is ≤5%.

Colon cancer in pregnancy with elevated maternal serum α-fetoprotein level at presentation

Whitney Gonsoulin, MD, Brian Mason, MD, and Robert J. Carpenter, Jr., MD
Houston, Texas

A case of colon cancer in pregnancy is presented in which the maternal serum α-fetoprotein level was elevated. Failure to evaluate colon cancer as a cause of the elevated maternal serum α-fetoprotein may have accounted for the poor outcome. (Am J Obstet Gynecol 1990;163:1172-3.)

Key words: Colon cancer, pregnancy, α-fetoprotein

The use of maternal serum α-fetoprotein (AFP) testing as a screening method for the early detection of fetal anomalies and chromosomal defects has increased in recent years. However, a variety of nonobstetric diseases may also elevate maternal serum AFP values and this knowledge can assist the practitioner in the early detection of these disorders. We present a case report of a patient with adenocarcinoma of the colon during pregnancy in which the first abnormality noted was elevated maternal serum AFP.

Case report

A 33-year-old white primigravid woman had routine prenatal care without apparent complications. At 16 weeks the maternal serum AFP level was 198.6 mg (6.2 multiples of the median). Ultrasonography was normal at 17 weeks and amniocentesis showed normal level of amniotic AFP and negative acetylcholinesterase. Chromosome analysis showed a normal 46,XY pattern.

At 23 weeks' gestation the patient was seen for complaints of epigastic pain. She denied nausea or vomiting, change in bowel habits, or melena. Initial medical therapy was unsuccessful. Physical examination showed a mass in the epigastrum and left upper quadrant. A liver ultrasound demonstrated a large liver mass. Magnetic resonance imaging showed an enlarged liver with the appearance of a multifocal hepatoma occupying both right and left lobes. A liver biopsy was performed at 25 weeks that revealed an adenocarcinoma of unknown origin. Carcinoembryonic antigen was significantly elevated at 630 ng/dl and gastrointestinal malignancy metastatic to the liver was considered.

From the Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, Baylor College of Medicine.
Received for publication March 6, 1990; revised March 27, 1990; accepted May 1, 1990.
Reprint requests: R. J. Carpenter, Jr., MD, 6550 Fannin St., 901, Houston, TX 77030.
6/1/22090

At 25 weeks' gestation, the patient was transferred to our tertiary center with complaints of abdominal pain, shortness of breath, and vomiting. Physical examination was remarkable for a grossly distended abdomen with ascites. Colonoscopy revealed a large fungating, friable mass approximately 15 cm in length in the midtransverse colon occluding 80% of the lumen. Biopsies confirmed invasive adenocarcinoma similar to that of the liver biopsy. Obstetric ultrasonography was performed and confirmed a viable singleton pregnancy without anomalies.

The patient's physical condition deteriorated rapidly and she became progressively more lethargic and anorexic. On the seventh hospital day, fetal heart tones could not be auscultated and fetal death was confirmed by ultrasonography. Labor was induced without difficulty. Postpartum the patient became oliguric and developed gram-negative septicemia confirmed by blood cultures. Despite antibiotic therapy and replacement of clotting factors, the patient's coagulopathy persisted and progressive oliguria and ascites developed. The patient died after cardiopulmonary arrest on hospital day 21.

Necropsy on the fetus revealed an 890 gm male infant without congenital abnormalities. Study of the placenta showed acute inflammation of the decidua and chorion without metastases. Autopsy of the mother revealed a 6530 gm liver with 95% of the liver parenchyma replaced by necrotic tumor and an adenocarcinoma of the transverse colon measuring 4.5 × 6 cm.

Comment

As more women are screened with maternal serum AFP level determinations, physicians are confronted with unexplained elevations of maternal serum AFP values. Causes for elevation include a variety of obstetric conditions including neural tube defects, abdominal wall defects, multiple gestation, Rh isoimmunization, improper dates, and intrauterine death. In addition, there are a number of nonobstretic disease processes that can cause elevations in maternal serum

AFP such as hepatitis, infectious mononucleosis, liver, stomach, and colon cancer.[1]

In this case, marked elevations in the maternal serum AFP level were probably related to the primary adenocarcinoma or the hepatic metastases. Unfortunately, symptoms of early pregnancy can be confused with the symptoms of colon cancer, which include rectal bleeding, constipation, persistent abdominal pain, or a rectal or an abdominal mass. Screening tests such as carcinoembryonic antigen assay are often elevated in pregnancy and are therefore of limited use in diagnosis of colon cancer in pregnancy. The majority of colon cancers occur below the peritoneal reflection and can be diagnosed by rectal examination. For higher lesions, sigmoidoscopy or colonoscopy may be necessary. Early detection and treatment greatly improves the prognosis of this disease.

The incidence of colon cancer in pregnancy is estimated to be in 1/50,000 to 1/100,000 pregnancies[2]; however, this number may be expected to rise as an increasing number of older women become pregnant. Unexplained elevations in maternal serum AFP, particularly in the face of normal amniotic fluid AFP, necessitates further workup to rule out potentially treatable causes.

Effects of hypertension on pregnancy monitoring and results

Jack W. Lenox, MD, Valentine Uguru, MD, and Luis A. Cibils, MD
Chicago, Illinois

The effect of severity of hypertension on fetal heart rate tracing changes and neonatal outcomes was evaluated on all patients with hypertension seen in 1980 and 1981 (666 cases, 10% of the pregnant population) in the Chicago-Lying In Hospital. The patients were grouped according to severity of hypertension, and the fetal heart rate monitoring, drugs administered, mode of delivery, and neonatal outcome were analyzed. Half of the patients (326) had mild hypertension and 13% (87) had severe hypertension; the remainder (253) had moderate hypertension. There were 49% primiparous and 51% multiparous women. The diagnosis of preeclampsia was made in 76% of cases, and chronic hypertension in 19%. Only 2% of the total were premature by dates, but 47% of this group were among the severe group. Oxytocin was given to 50%, whereas delivery was spontaneous in 56% of cases, and by cesarean section in 22%. This was higher among the severe hypertension group (37%), and the prematurity rate was 47%. Nonstress testing was done in one third of cases and only nonreactivity was associated with neonatal death. Neonatal depression (Apgar score < 6 at 5 minutes) was significantly associated with intrapartum fixed baseline and late decelerations; these were the best predictors of fetal outcome. The administration of magnesium sulfate, hydralazine, meperidine, or morphine did not predictably affect the fetal heart rate pattern. The perinatal mortality was 21‰ in the mild group and 36‰ and 138‰, respectively, among moderate and severe cases of hypertension. Close antepartum and intrapartum surveillance, including proper fetal monitoring, should help to reduce risks for mother and fetus through timely intervention. (AM J OBSTET GYNECOL 1990;163:1173-9.)

Key words: Hypertension, fetal heart rate, monitoring

Pregnancies complicated by hypertension have been extensively studied, with increased complications noted in cases of intrauterine growth retardation,[1-3] fetal distress,[4-7] and perinatal mortality.[2,3,8,9] Prospective studies have shown that the likelihood of poor fetal outcome increases as the severity of hypertension increases.[8,10] The most common reason suggested for these complications postulates a decreased perfusion of the intervillous space as a result of peripheral vasoconstriction

Group 3	87 (13%)	8 (57%)	12 (55%)	21 (47%)	44 (8%)	2 (6%)	47
TOTAL	666 (100%)	14 (2%)	22 (3%)	45 (7%)	551 (83%)	34 (5%)	

that ultimately produces placental insufficiency. This decreased perfusion would be reflected during the antenatal period or in labor by abnormal fetal heart rate (FHR) patterns that are known to occur in some hypertensive pregnancies.[4] This study is a retrospective analysis of the effect of the severity of hypertension on FHR patterns and fetal outcome, as well as an evaluation of commonly administered medications and their effects on intrapartum FHR patterns. The minimal blood pressure reading chosen to indicate hypertension of pregnancy was 125/75 mm Hg in view of the relatively recently acquired knowledge that in the last two trimesters of human pregnancy the normal blood pressure fluctuates around 100/60 mm Hg with very narrow ranges, and that preeclampsia has been regularly described with readings of 125/75 mm Hg.[11]

Material and methods

The study group consisted of all pregnant women with hypertension, defined as blood pressure of >125/75 mm Hg, after the fifth month of gestation. All patients were delivered at the Chicago-Lying In Hospital between Jan. 1, 1980, and Dec. 31, 1981. The medical records of the study group were reviewed (by U. V.) of the 666 patients who fulfilled the criteria, and 80 parameters were extracted. This population was divided into three subgroups based on the severity of hypertension. Patients in group 1 had blood pressure recordings between 125/75 and 135/85 mm Hg (n = 326, 49% of cases); group 2 patients had blood pressure readings from 136/86 up to 150/100 mm Hg (n = 253, 38%); group 3 patients had blood pressure measurements >150/100 (n = 87, 13%).

The intrapartum FHR tracings were reviewed (by J. W. L.) in 451 of these patients for whom they were available. These FHR tracings were analyzed to determine the type of decelerations (if any) present (early, variable, late), the baseline rate (normal, 120 to 150 beats/min), and the alterations of the baseline pattern (normal oscillations, fixed, saltatory).[4]

Prenatal care was given at Chicago-Lying In Hospital to 564 patients (85%); of the remainder, 61 patients (9%) received either no prenatal care or prenatal care was provided at local clinics or offices, and 41 (5%) were transferred from other hospitals. Maternal ages ranged between 13 and 45 years; 29% (n = 191) were between 13 and 19 years; 47% (n = 310) between 20 and 29 years; 22% (n = 149) between 30 and 39 years; and 2% (n = 16) were over 40 years of age. There were approximately equal numbers of primiparous (n = 327) and multiparous (n = 339) patients. The majority of patients were black (n = 633), with whites (n = 25) and other ethnic backgrounds (n = 8) present in much smaller numbers.

The patients were given a diagnosis of preeclampsia (n = 503), eclampsia (n = 4), chronic hypertension (n = 128), renal disease (n = 19), and "other" diagnosis (n = 12), including sickle cell disease, epilepsy, idiopathic thrombocytopenic purpura, etc., according to standard clinical criteria. Labor was spontaneous in 241 patients (36%), induced in 200 (30%), and enhanced in 130 patients (20%). There was no labor in 75 cases (11%), and 20 cases were uncoded (3%). Preterm deliveries (≤36 weeks) occurred in 81 patients (12%), whereas 551 pregnancies (83%) were term (37 to 41 weeks), and 34 (5%) were ≥42 weeks from the last menstrual period.

All data from the chart review and the data from the FHR tracings analysis were entered into a computer for statistical analysis, usually with the χ^2 test.

Results

The total number of women delivered at Chicago-Lying In Hospital during the study period (1980 and 1981) was 6648, of which 666 were classified as hypertensive, for a 10% incidence of hypertension (as defined here) in the population.

Table I shows the gestational ages of the patients in each study group. Patients in groups 2 and 3 accounted for 80% of all preterm deliveries (≤36 weeks) and 85% of deliveries at ≤32 weeks' gestational age. Table II shows the type of delivery for each group; it is of interest that, as the severity of hypertension increased there was an increase in the cesarean section rate, a decrease in the spontaneous delivery rate and, essentially, no difference in the rate of forceps or vacuum deliveries ($p < 0.001$). Furthermore, 22% of the cesarean sections occurred in group 3 patients (Table III), 37% of whom were delivered by this route (Table II), even though this group constitutes only 13% of the total population. The indications for intervention were analyzed for each study group among the patients who

had cesarean section (Table III). A higher percentage of cesarean sections was performed in patients in group 3 for fetal indications than in groups 1 or 2. The majority of these cases involved fetal distress, determined by either antepartum heart rate monitoring (nonstress test–contraction stress test), falling estriol levels, intrapartum decelerations, or low fetal scalp pH values. The majority of patients in groups 1 and 2 who had cesarean deliveries for maternal indications were patients with previous cesarean deliveries.

A higher percentage of group 3 fetuses exhibited late decelerations (11%) as compared with those in group 1 (5%) or 2 (4%), although this difference was not significant. A similar occurrence was observed at evaluation of the baseline rate, with no significant differences among the hypertensive groups, although a higher percentage of group 3 fetuses (13%) did have baseline tachycardia than those in groups 1 (7%) and 2 (8%). As the severity of hypertension increased, significantly more fetuses within each group exhibited a sustained fixed baseline ($p < 0.03$) as shown on the left side of Fig. 1.

To determine whether the duration of hypertension influenced the FHR patterns recorded during labor, a comparison was made between patients with preeclampsia (presumably shorter time) and those diagnosed as having chronic hypertension. There were no differences between these two groups in the incidence of type of decelerations observed, the baseline rate, or baseline alterations. The data shown in Fig. 1 suggest that the degree of hypertension is a more important determinant of abnormal FHR patterns than is the duration of hypertension.

The effects of intrapartum medications on the FHR patterns were analyzed for the various FHR parameters and were grouped according to the medications the patients received during labor. There were no significant differences in the types of decelerations recorded when patients who received no medication were compared with those who received either magnesium sulfate, hydralazine, or sedatives, although a higher percentage of fetuses in the hydralazine group did have late decelerations compared with the other groups. Similarly, there were no differences when the baseline rate was analyzed among the patients who received no medications and those who were medicated. However, when analyzed for effect on baseline patterns a significantly higher ($p < 0.001$) number of fixed baseline tracings were found in the groups that received hydralazine and magnesium sulfate than in the groups that received no medication or sedatives (Fig. 2). Because an increase in fixed baseline tracings was also observed as the severity of hypertension increased (Fig. 1), it may have been possible that administration of magnesium sulfate and hydralazine accounted for this increase. However, when each hypertensive group was analyzed for the type of intrapartum medications received (Table IV), the percentage of patients who received magnesium sulfate was nearly the same in each group, whereas the percentage of patients who received hydralazine did increase with increasing hypertension. The last finding suggests that although magnesium sulfate does not appear to affect baseline, the conditions that make it necessary to administer hydralazine may influence baseline patterns.

The results of nonstress tests performed on each hypertensive group are listed in Table V. There were significantly more nonreactive tracings in patients in group 3 than in patients in group 1 or 2 ($p < 0.005$); in fact, 31% of all patients in group 3 were nonreactive, and there were two neonatal deaths among this group. In group 2 patients there was one neonatal death

among the nine patients who had fetuses with nonreactive tracings.

A total of 47 infants (7%) among all the study groups (including cesarean sections) were depressed at birth (Apgar score ≤ 6 at 5 minutes). Among those who had intrapartum tracings, the incidence of late decelerations in the depressed group was significantly higher (24%) than in the group with Apgar scores ≥ 7 at 5 minutes (4%) ($p < 0.005$). There were no significant differences in baseline rate between the two infant groups. However, a higher percentage of infants with low Apgar scores did have fixed baselines compared with those with Apgar scores ≥ 7 (Table VI). These findings suggest that, as in normotensive pregnancies, the presence of abnormal FHR patterns can serve as a warning that the infant may be depressed at birth. The perinatal mortality rate was calculated for each group (Table VII) to assess the overall effect of the severity of hypertension on the fetus. A marked rise in perinatal mortality was seen as the severity of hypertension increased. The more severely hypertensive groups (2 and 3) accounted for 83% of all stillbirths and 69% of all neonatal deaths. Causes of death of the 16 infants were as follows: respiratory distress syndrome, seven; intracranial hemorrhages, eight; and sepsis, one. The perinatal mortality rate for all patients who were delivered at Chicago-Lying In Hospital in 1980 and 1981 was 43 per 1000; this included all deaths regardless of birth weight, and encompassed patients with a variety of high-risk conditions. There was one maternal death in the study group in a patient with eclampsia at 26 weeks' gestation who probably received an excessive dose of magnesium sulfate.

Comment

Intrapartum FHR patterns in term hypertensive pregnancies were previously reported by comparison with normotensive controls.[4] In this study a comparison was made among groups of hypertensive gravid women to evaluate the effect of the degree of hypertension on the FHR patterns. A trend of higher incidence of late decelerations was seen among group 3 patients than among those with lower blood pressures. However, as in normotensive pregnancies, the presence of late decelerations foretells difficulty for the fetus as demonstrated by the 24% of cases with Apgar scores ≤ 6 at 5 minutes that had late decelerations, significantly higher than among those with Apgar scores ≥ 7 (only 4%).

Higher blood pressure resulted in a trend toward an increasing percentage of fetuses who experienced intrapartum tachycardia. A relative fetal tachycardia during the third trimester has been reported to occur before the development of maternal hypertension.[12] A prospective analysis of the fetal heart rate from 15 to 38 weeks' gestation has shown a higher rate in those gestations in which hypertension ultimately developed.[13] However, no differences in the incidence of fetal tachycardia between hypertensive and normotensive gravid women at term has been previously reported.[4] The higher percentage of cases of fetal tachycardia with increasing blood pressure as shown in this study may not be a result of fetal distress but instead the higher incidence of preterm infants in the group 3 patients (Table I). This suggestion is supported by the observation that the incidence of fetuses with tachycardia was the same in infants with Apgar scores ≤ 6 and those with higher scores.

Perinatal mortality in hospital, 1980 and 1981, 43/1000.

The presence of a fixed baseline appears to portend an unfavorable prognosis for the newborn, as has been previously reported in normotensive[14, 15] and hypertensive pregnancies.[16] The incidence of fetuses with fixed baseline increased significantly ($p < 0.03$) in parallel with the severity of the hypertension (Fig. 1). A significantly higher number of infants with Apgar scores ≤ 6 also displayed that pattern, compared with those with higher scores ($p < 0.006$). The finding that neonatal death occurred only among infants who had nonreactive antenatal tracings was probably of equal importance. Although this last finding was not significant, there was only a small number of infants to analyze; perhaps with a larger number statistical significance would have been achieved.

The intrapartum administration of magnesium sulfate or sedatives (meperidine, morphine) was found to have little effect on the FHR patterns. The incidence of fetal tachycardia was insignificantly higher among those patients who received magnesium sulfate but, as previously reported,[4] the tachycardia probably preceded the administration of the drug. The same pattern was observed among those patients who received sedatives. This finding reflects the previously shown[4] negligible effects of these drugs on FHR baseline frequency. Use of magnesium sulfate has been reported to increase,[17] decrease,[18] or have no effect[4] on FHR variability. The changes in variability, if any, caused by magnesium sulfate are probably transient as indicated by others[16, 18] because in this study only 23% of patients who received magnesium sulfate (164) had fixed baseline tracings (Fig. 2); the severity of hypertension was a more important factor in these patients than was the magnesium sulfate. Administration of hydralazine usually does not cause changes in FHR patterns unless maternal hypotension is induced, resulting in late decelerations. Patients who received hydralazine did have an increase in late decelerations and fixed baseline tracing (Fig. 2). This could have been related to the fact that the need to administer the antihypertensive agent increased as the severity of hypertension increased, as shown in Table IV.

The perinatal mortality rates for the study groups correlate well with previous publications[8, 19] that have shown a corresponding increase in perinatal mortality as the mean arterial pressures rise. The increasing stillbirth rate with increasing severity of hypertension, regardless of the cause, indicates that close attention must be paid during the antepartum period to the well-being of the fetus. The higher incidence of abnormal intrapartum FHR patterns, especially fixed baseline tracings or the presence of late decelerations, and the resultant increase in neonatal deaths in the more severely hypertensive patients indicates the need for extremely close monitoring of the fetus. It would be advisable to use a fetal scalp electrode and an intrauterine pressure catheter to obtain the most reliable monitoring tracing, and when abnormal FHR patterns are detected the fetal scalp pH should be assessed whenever possible.

The following conclusions can be made on the basis of these findings.

1. Continuous fetal heart rate monitoring, properly recorded and interpreted, may indicate the fetuses at higher risk in hypertensive conditions.
2. A fixed baseline and late decelerations seem to be the two best predictors of a depressed neonate. Neonatal death was associated only with nonreactive NST.
3. Nearly one half of patients with severe hypertension were delivered prematurely, and more than one third were delivered by cesarean section.
4. The overall incidence of cesarean section delivery

was 22%, many of which were repeat operations, whereas more than half the patients were delivered spontaneously.

5. Drugs commonly used in management of hypertension do not predictably affect FHR patterns unless they trigger maternal hemodynamic changes.
6. The perinatal mortality among hypertensive patients was similar to the overall perinatal mortality of the hospital. However, there was an eightfold increase in the severely hypertensive group.
7. Close antenatal and intrapartum surveillance may help to reduce the risks for both mother and infant.

Spontaneous infarction of placental chorioangioma and associated regression of hydrops fetalis

Cynthia Chazotte, MD, Barbara Girz, DO, Mordecai Koenigsberg, MD, and Wayne R. Cohen, MD

Bronx, New York

We report a case of a large chorioangioma diagnosed prenatally with concomitant meconium peritonitis and hydrops fetalis in the second trimester. Spontaneous regression of the tumor occurred, associated with some resolution of the fetal hydrops and delivery near term with good neonatal outcome. (Am J Obstet Gynecol 1990;163:1180-1.)

Key words: Chorioangioma, meconium peritonitis, nonimmunologic hydrops

Chorioangioma is the most common primary tumor of the human placenta. Nonimmunologic hydrops fetalis is a serious fetal complication associated with this neoplasm.[1] We diagnosed a large chorioangioma by ultrasonography in the second trimester that was associated with meconium peritonitis and hydrops fetalis. Spontaneous resolution of the tumor coincident with some resolution of the hydrops occurred.

Case report

A 24-year-old woman (gravida 3, para 0-1-1-1), was referred for fetal ultrasonographic examination at 20 weeks' gestation because of maternal congenital heart disease. The mother was Rh-negative without antibodies. The VDRL test was negative, and there was no history suggestive of other TORCH infections. Previous pregnancies resulted in a spontaneous first-trimester abortion and a vaginal delivery of a healthy infant at 36 weeks' gestation.

Ultrasonography revealed fetal measurements consistent with gestational age, no identifiable anomalies, and normal amniotic fluid volume. The posterior placenta had a localized area of thickening, which was thought to possibly be a chorioangioma. Repeat ultrasonography at 23 weeks' gestation showed obvious hydramnios, with placental and fetal subcutaneous edema, ascites, and a highly echogenic intraabdominal region (Fig. 1). A 5 × 6.5 × 5.5 cm chorioangioma was recognizable on the fetal surface of the placenta. The patient elected to continue the pregnancy but declined to allow any diagnostic or therapeutic interventions.

Subsequent serial ultrasonographic examinations every 10 to 14 days showed gradual regression of the placental tumor and fetal subcutaneous edema, but persistent fetal ascites and echogenic regions. Nonstress tests performed semiweekly beginning at 29 weeks' gestation were always reactive. Delivery of a 3300 gm infant with Apgar scores of 7 and 8 at 1 and 5 minutes, respectively, occurred at 35 weeks' gestation after spontaneous rupture of membranes. There was no evidence of coagulopathy or anemia at birth. Postnatal ultrasonographic and x-ray examinations confirmed ascites and calcifications in the abdomen consistent with meconium peritonitis. There were no perforations seen on gastrointestinal series. The infant had a normal neonatal course including normal gastrointestinal function, with resolution of his ascites. He has had normal growth and development in the first year of life. The 620 gm placenta had a 5 × 5 cm soft, friable lesion on the fetal surface near the cord insertion. Histologic examination of this area was consistent with focal infarction of a preexisting chorioangioma.

Comment

Hydrops fetalis of any cause is generally associated with an adverse prognosis and often prompts early delivery or even induced abortion. Both chorioangioma and meconium peritonitis have been found in association with this entity.[1, 2] In this case both conditions could have contributed to the hydrops. However, although meconium peritonitis may explain the ascites and polyhydramnios, it is unlikely that it would cause subcutaneous or placental edema. It is not clear whether the presence of the chorioangioma and meconium peritonitis was coincidental. It is possible that

the meconium peritonitis may have been caused by a vascular thrombosis in the developing gastrointestinal tract, related to the chorioangioma. This possibility is supported by the fact that the tumor was a degenerative chorioangioma, a histologic variant frequently associated with intravascular thrombosis and infarction.

This case is significant in two respects. First, we observed the spontaneous infarction and gradual regression of a large chorioangioma with ultrasound imaging. Second, we demonstrated a partial resolution of pathologic fetal fluid associated with the regression of the angioma. Thus the prognosis for the hydropic fetus in the second trimester is not necessarily poor when a chorioangioma or meconium peritonitis has been identified.

Ovarian pregnancy: A report of twenty cases in one institution

Arieh Raziel, MD, Abraham Golan, MD, Mordechai Pansky, MD, Raphael Ron-El, MD, Ian Bukovsky, MD, and Eliahu Caspi, MD

Tel Aviv, Israel

A series of 20 cases of primary ovarian pregnancy that were diagnosed and treated in one institution is reported. The prevalence rate of 1:3600 deliveries seems to be increasing in past years and comprises 3.3% of all extrauterine pregnancies. Clinical presentation, possible pathogenesis, diagnostic steps, preferred management, and future fertility are detailed. Inasmuch as all our 18 fertile patients used an intrauterine contraceptive device before the operation, special emphasis is made on the controversial relationship between use of intrauterine contraceptive devices and ovarian pregnancy. (AM J OBSTET GYNECOL 1990;163:1182-5.)

Key words: Ovarian pregnancy

Primary ovarian pregnancy is one of the rarest types of extrauterine pregnancy. It is reported as 1:7000 to 40,000 deliveries and <3% of all ectopic gestations.[1-4] Because of the increased vascularity of the ovarian tissue, ovarian pregnancy usually is first seen with nonspecific signs and symptoms of ectopic pregnancy, often with hemoperitoneum that requires emergency surgery. With few exceptions, the suggestive initial diagnosis is made on the operating table and the final diagnosis only by histopathology on the basis of the four Spiegelberg criteria[5] establishing that the pregnancy is limited to the ovary and does not involve the tube. As such, great interest has always been focused on attempts to suggest the diagnosis of ovarian pregnancy *preoperatively*.[6] The evidence that the intrauterine contraceptive device (IUD) is involved in the pathogenesis of this rare but challenging condition continues to increase.[7-10]

In this study we report a series of 20 cases of primary ovarian pregnancy, all diagnosed and treated in one institution. The prevalence, presentation, possible pathogenesis, relation to the IUD, treatment, and results are discussed.

Material and methods

The medical records of 20 cases of ovarian pregnancy that occurred during a 19-year period (1971 to 1989) at Assaf Harofeh Medical Center, Zerifin, Israel, are reviewed. Pertinent data on each of the patients first seen before surgery are summarized in Table I.

6/1/22988

Results

During these years there were 75,272 deliveries, of which 637 were ectopic pregnancies, comprising 0.85% of the total number of deliveries. A total of 21 cases (3.3%) of ectopic pregnancies were primary ovarian pregnancies for prevalence rate of 1:3600 deliveries. The prevalence is not constant but seems to be increasing, inasmuch as 10 cases occurred between 1971 to 1984 and 11 cases between 1985 to 1989, constituting a prevalence rate of 1:2100 in the past 5 years. One case that occurred in 1986 was included for prevalence calculation but was excluded from the series because of incomplete records. No particular past illness was reported. Four of the 21 patients had undergone abdominal surgery: three appendectomies and one explorative laparotomy after a road accident. A total of 90% of the women were multiparous with a mean age of 28 years (range, 20 to 34 years). The rate of associated use of IUD was extremely high, 18 of the 20 patients. The remaining two patients were nulligravid, one patient with 11-year primary infertility because of male factor and the second patient with 2 years of unexplained infertility. In fact, there was no case of ovarian pregnancy associated with a fertile woman who did not use an IUD. Signs and symptoms are detailed in Table II. Abdominal pain was present in almost all cases (95%) combined with menstrual irregularity (70%). Circulatory collapse occurred in six patients (30%). Other signs and symptoms are similar to those recorded in other tubal pregnancies. The mean duration from the last menstrual period to surgery was 6.3 weeks (range, 5 to 7.5 weeks). All cases since 1982 (13 of 20) had quantitative serum human chorionic gonadotropin β-subunit (β-hCG) determinations. In five patients the β-hCG level was <250 mIU/ml. The lowest value measured was 53 mIU/ml.

Surgical data including preoperative diagnosis, diagnostic procedures, operative diagnosis, and management are shown in Table III. Thirteen patients (65%) were suspected of having an ectopic pregnancy. Three (15%) were diagnosed as having a ruptured corpus luteum. Ovarian pregnancy was incidentally found in two cases: one at laparoscopy for suspected pelvic inflammatory disease and one at laparotomy for an acute abdomen not being aware of her pregnancy (before the era of β-hCG measurements). A Douglas puncture was performed in 12 of 20 cases (60%). Laparotomy followed a laparoscopic examination in nine patients (45%) and was directly performed without laparoscopy in 11 patients (55%). These laparotomies were preceded by a Douglas puncture in nine patients (82%). The ovarian pregnancy was equally distributed, 11 in the right ovary and nine in the left. Endometriotic implants were not found in any case. Estimated blood loss of ≥500 ml was found in 60% of patients. Blood transfusion was necessary in 35% of cases. Ovarian wedge resection was the most frequent surgical procedure performed (75%). In two of the patients who underwent salpingo-oophorectomy, tubal ligation was carried out for sterilization at the patients' preoperative request. Appendectomy was not frequently performed (15%). In no case was oophorectomy performed as a sole procedure. The final diagnosis was established by the histopathologic examination according to Spiegelberg's principles.[5]

Table II. Clinical presentations

Symptoms	Patients	%
Abdominal pain	19/20	95
Menstrual irregularity	14/20	70
Palpable adnexal mass	8/20	40
Circulatory collapse	6/20	30

Of the 18 fertile patients, four were lost to follow-up and six used various methods of contraception so that fertility could be followed up in only eight patients (40%). Of these, one had a tubal pregnancy and seven had uneventful intrauterine pregnancies.

Comment

An increase in the reported prevalence of ovarian pregnancies was published in recent years.[11, 12] Grimes reported on one ovarian pregnancy per 7000 deliveries and <3% of all ectopic pregnancies.[4] This corresponds well with our reported prevalence. It is not absolutely clear whether this is a true increase in prevalence or simply diagnosis of more ovarian pregnancies as a result of more awareness of this rare ectopic site, more tissue biopsy specimens from bleeding ovaries sent for histopathologic examination, and probably an early diagnosis of cases that would have otherwise resolved spontaneously, as happens in a certain proportion of tubal pregnancies.[13]

OP, Ovarian pregnancy; *DP,* Douglas puncture; *EP,* ectopic pregnancy; *CL,* corpus luteum; *PID,* pelvic inflammatory disease; *WR,* wedge resection; *LSO,* left salpingo-oophorectomy; *RSO,* right salpingo-oophorectomy.

Early quantitative serum β-hCG measurements, early pelvic ultrasonography, and particularly use of the vaginal probe showing "empty" uterus combined with symptomatology of ectopic pregnancy lead to more laparoscopies to find the site of ectopic gestation. An intact fallopian tube at laparoscopy with hemorrhagic ovary require a laparotomy and at least a wedge resection and hemostatic suturing.

The cause of primary ovarian pregnancy remains obscure. Boronow[14] concludes that chance is the reasonable explanation of ovarian pregnancies. Other hypotheses have suggested interference in the release of the ovum from the ruptured follicle, malfunction of the tubes, inflammatory thickening of the tunica albuginea, and parthenogenesis. In contrast to patients with tubal pregnancies, those with ovarian pregnancies very seldom have a history of pelvic inflammatory disease. In our series, no woman reported a past pelvic inflammatory disease, and at surgery we rarely found pelvic adhesions. Similar findings were reported by Sandevi et al.[10] and Chilanda,[11] but are in contradiction with Grimes et al.[4] who reported a previous reproductive system pathology or infertility in more than half their 24 cases.

The relationship between the IUD use and ovarian pregnancy is not new, but is very controversial. In 1970 Lehfeldt[15] conducted a survey of women who became pregnant while using an IUD and by simple mathematic extrapolation concluded that the IUD prevents implantation in the uterus with 99.5% effectiveness and in the tube with 99%, but that it has no effect on ovarian implantation. Grimes et al.,[4] in their literature overview until 1983, reported on ≤25% concurrent use of an IUD and ovarian pregnancy. Seventeen cases of 25 (68%) had an IUD in situ in Sandevi's recent study published in 1987.[10] In our series, 18 of 20 women (90%) had an IUD in situ when ovarian pregnancy was diagnosed, with an average duration of use of 2 years and a range of 6 to 54 months. The remaining two women were infertile before and remained so after

surgery. Thus all the fertile women in our series used an IUD at the occurrence of ovarian pregnancy. This fact strongly suggests that the IUD is somehow involved in the pathophysiology of ovarian pregnancy. Ovarian endometriosis does not seem to be an important causative factor, inasmuch as we found no evidence of the disease in any of our cases. This was also confirmed by others.[12]

Most ovarian pregnancies are symptomatic with abdominal pain being the most frequent sign along with menstrual irregularity. There was only one asymptomatic case in our series in which the ovarian pregnancy was associated with a contralateral torted ovarian cyst that could have masked the clinical presentation of the ovarian pregnancy.

The clinical presentation is usually more dramatic than that in tubal pregnancies. Because of the increased vascularity of the ovarian tissue and the growing gestation, rupture of the ovary and hemoperitoneum usually occur. Circulatory collapse may ensue rapidly (30% in our series) and even when the circulating system still holds, signs and symptoms of acute hemoperitoneum may become evident and immediate laparotomy is indicated, as in the majority of our patients. A Douglas puncture seems to be an important diagnostic tool. Hemoperitoneum was found in 95% of our cases with an average blood loss of 730 ml. Grimes et al.[4] reported that the prevalence of rupture among the ovarian pregnancies in his series was 91.6% and the average blood loss was 885 ml.

With the improvement of ultrasonographic skill and instrumentation, especially the vaginal probe, ovarian pregnancy has been recently demonstrated preoperatively.[16, 17] A live embryo within the ovary was demonstrated in one of our cases (no. 8), but because of clinical signs of shock there was no time for ultrasonographic examination. Despite the limited aid of ultrasonography in preoperative diagnosis in this series, we believe that vaginal ultrasonography may potentially be a very helpful diagnostic tool.

No case of repeat ovarian pregnancy has been reported in contrast to the approximate 15% recurrent tubal pregnancy rate.[18] In contrast to the tube, rupture of the ovary is a frequent phenomenon occurring periodically at ovulation. In view of this and the fact that seven intrauterine pregnancies were reported among the eight fertile patients after surgery, we agree with Portuondo[19] and others who believe that fertility after an ovarian pregnancy remains unmodified.

Ultrasonographic detection of the second-trimester fetus with trisomy 18 and trisomy 21

Norman Ginsberg, MD, Alan Cadkin, MD, Eugene Pergament, MD, PhD, and Yury Verlinsky, PhD

Chicago, Illinois

Biparietal diameter/femur length ratio and nuchal thickness were found to be sensitive indicators for the prenatal detection of trisomy 18 and trisomy 21. A biparietal diameter/femur length ratio >1.5 SD above the control mean correctly identified 5 of 11 (46%) fetuses with trisomy 21 and 3 of 4 (75%) fetuses with trisomy 18. Nuchal thickening (6 mm or more) correctly identified 5 of 12 (41%) fetuses with trisomy 21 and 2 of 4 (50%) fetuses with trisomy 18. The sensitivity and specificity of the biparietal diameter/femur length ratio in detecting either aneuploidy was 53% and 93%, respectively, whereas a thickened nuchal fold had a sensitivity of 44% and a specificity of 100%. The combined use of the two ultrasonographic measurements had an overall sensitivity of 81% and a specificity of 93%. Prospective ascertainment of these two trisomies appears warranted in low-risk populations. (Am J Obstet Gynecol 1990;163:1186-90.)

Key words: Trisomy 18, trisomy 21, ultrasonographic screening, fetus

Prenatal genetic studies to detect chromosomally abnormal conceptions have generally been limited to women of advanced maternal age and those who have experienced a previous conception with a chromosomal aberration. However, it is young mothers with completely normal pregnancy histories who subsequently are delivered of the largest number of chromosomally abnormal newborns. Although their individual risk for such an occurrence is very small, women younger than 34 years of age have >80% of all affected pregnancies. For this reason less than 20% of all trisomy 21 pregnancies could potentially be detected prenatally by means of chorionic villus sampling or amniocentesis.[1]

An important benefit to the screening of pregnancies for open neural tube defects is the recognition that a low concentration of maternal serum α-fetoprotein (AFP) may be associated with trisomy 21.[2] Critical assessment of the effectiveness of these screening programs reveals their disappointing low sensitivity (12% to 21%) as well as high false-positive rate (7% to 9%).[2, 3]

Recently the combination of maternal serum AFP, β-subunit human chorionic gonadotropin, and serum estriol have shown promise for greater detection of Down syndrome than maternal serum AFP alone.[4-6]

It has been reported that biparietal diameter/femur length ratio and nuchal skin thickness measurements can identify 50% to 70% of trisomy 21 pregnancies in the second trimester,[7, 8] but this has been disputed.[9, 10] This study confirmed that a combination of both measurements may be the most sensitive, noninvasive approach to the prenatal identification of trisomy 21 and can be successfully applied to the detection of trisomy 18 as well.

Material and methods

The ultrasonographic equipment used in this study consisted of an ATL Ultramark-4, Diasonics Wide Vu, and Acuson-128. All transducers were 3.5 mHz with a combination of arc sector and linear array.

The study group consisted of 12 cases of trisomy 21 and four cases of trisomy 18 previously diagnosed by amniocentesis. The control group comprised 212 randomly selected cases with a normal karyotype as determined by chorionic villus sampling or amniocentesis. The control group was used to establish a gestational curve for the biparietal diameter/femur length ratio. The control group biparietal diameter/femur length ratio then became the basis for comparison against the trisomic fetuses. The criteria for inclusion into the control group were either a first-trimester ultrasonographic evaluation confirming gestational age (determined by crown-rump length), or a second-trimester ultrasonographic evaluation confirming that the gestational age did not vary from the stated menstrual age by more than 1.5 weeks (determined by biparietal diameter and femur length measurements).[11, 12] All pa-

tients who underwent chorionic villus sampling had a similar ultrasonographic evaluation as those undergoing amniocentesis.

The biparietal diameter was measured with electronic calipers from leading edge to leading edge at the level of the thalami. The femus was measured in a plane that visualized the greater trochanter to the end of the ossified shaft. When there was a question regarding the exact placement of the markings by the electronic calipers, the acoustical shadow created by the ossified bone was used. For each of the trisomies the number of cases with a biparietal diameter/femur length ratio >1.5 SDs above the mean of the control for a given gestational age was determined. The selection of 1.5 SD above the mean of the controls was used to confirm the work of Lockwood et al.[7] as well as to check its applicability to trisomy 18.

The nuchal thickness was measured at both the level of the occiput, at the midpoint of the cerebellum in the transverse plane, as well as in the dorsal midsagittal plane at the same level, and was considered abnormal if >6 mm. One case of trisomy 21 was not included in the biparietal diameter/femur length analysis because the length of the femur was not measured in the original ultrasonographic evaluation; it was included in the analysis of nuchal thickness.

All abnormal cases were independently evaluated from videotapes by two of the authors (N. G. and A. C.) to assure measurement accuracy. Any differences in measurement were reevaluated and based on this review. Two femur length measurements were changed and one previously undiagnosed nuchal thickening was detected. The control group was also reviewed and no changes were made.

Results

The control value data are summarized in Table I. A biparietal diameter/femur length ratio >1.5 SDs above the control population mean was present in five of 11 (46%) fetuses with trisomy 21 and three of four (75%) fetuses with trisomy 18; there were 14 fetuses (6.6%) whose biparietal diameter/femur length ratios exceeded 1.5 SDs from their respective ratio means in the control population.

Five of the 12 (41%) fetuses with trisomy 21 and two of four (50%) fetuses with trisomy 18 had thickened (>6 mm) nuchal folds. There were no cases of occipital nuchal thickening ≥6 mm in the 212 fetuses that comprised the normal population.

If the data on the biparietal diameter/femur length ratio are combined with those of fetuses with a thickened nuchal fold nine of 12 (75%) fetuses with trisomy 21 and all four fetuses with trisomy 18 are identified, with a false-positive rate of 6.6%.

Table I. Control value for normal biparietal diameter/femur length ratio

Gestational age (wk)	*Normal biparietal diameter/femur length ratio (mean + 1.5 SD)*
14	1.96
15	1.83
16	1.72
17	1.66
18	1.65
19	1.63
20	1.64

The sensitivity (true-positive results) and specificity (true-negative results) of the two ultrasonographic measurements in the detection of either aneuploidy of chromosome 18 or 21 are summarized in Table II. The sensitivity and specificity of the biparietal diameter/femur length ratio was 53% and 93%, respectively. A thickened nuchal fold had a sensitivity of 44% and a specificity of 100%. The combined use of the two ultrasonographic measurements had an overall sensitivity of 81% and a specificity of 93%.

Comment

The biparietal diameter/femur length ratio and occipital nuchal thickness measurements can be used to detect a significant number of trisomic fetuses. When the biparietal diameter/femur length ratio with a 1.5 SD cut-off was applied, 75% of the fetuses with trisomy 18 were detected. A nuchal thickening of ≥6 mm was present in 50% of the fetuses with trisomy 18. By combining the use of these ultrasonic measurements, all four of these chromosomally abnormal fetuses were identified between 14 and 17 weeks' gestation.

The results of this study demonstrated remarkable agreement with those previously reported by Lockwood et al.[7] and Benacerraf et al.[8] despite the fact that each study established different normal values for the biparietal diameter/femur length ratio for each week of gestation. This strengthened the recommendation that each investigator needs to establish his or her own set of normal biparietal diameter/femur length ratios, which is dependent on their ultrasonographic equipment and their measurement techniques.[7]

The value of nuchal thickening in identifying fetuses with trisomy 21 in the second trimester of pregnancy has been questioned.[9] In this study a nuchal thickening of ≥6 mm was uniformly associated with aneuploidy and, in contrast to the previous report to Toi et al.,[9] there were no false positives in the control group. Moreover, the demonstration of nuchal thickening was clearly more indicative of the presence of a chromosomal abnormality than was a biparietal diameter/femur length ratio >1.5 SDs from the control mean. Mea-

*Ratio value > 1.5 SDs from normal mean.
†Nuchal thickness > 6 mm.

surement was taken in a plane at the level of the occiput, as described by Benacerraf et al.[13] from the outer skin line to the outer edge of the occipital bone. A thickened curvilinear extension of the skin line toward the level of the convexity of the parietal temporal complex (Fig. 1) associated with the abnormal thickening. This curvilinear line should not be confused with the head abutting against the amniotic membrane, particularly when there is an ultrasonographically residual chorioamniotic space. If there was any question as to whether

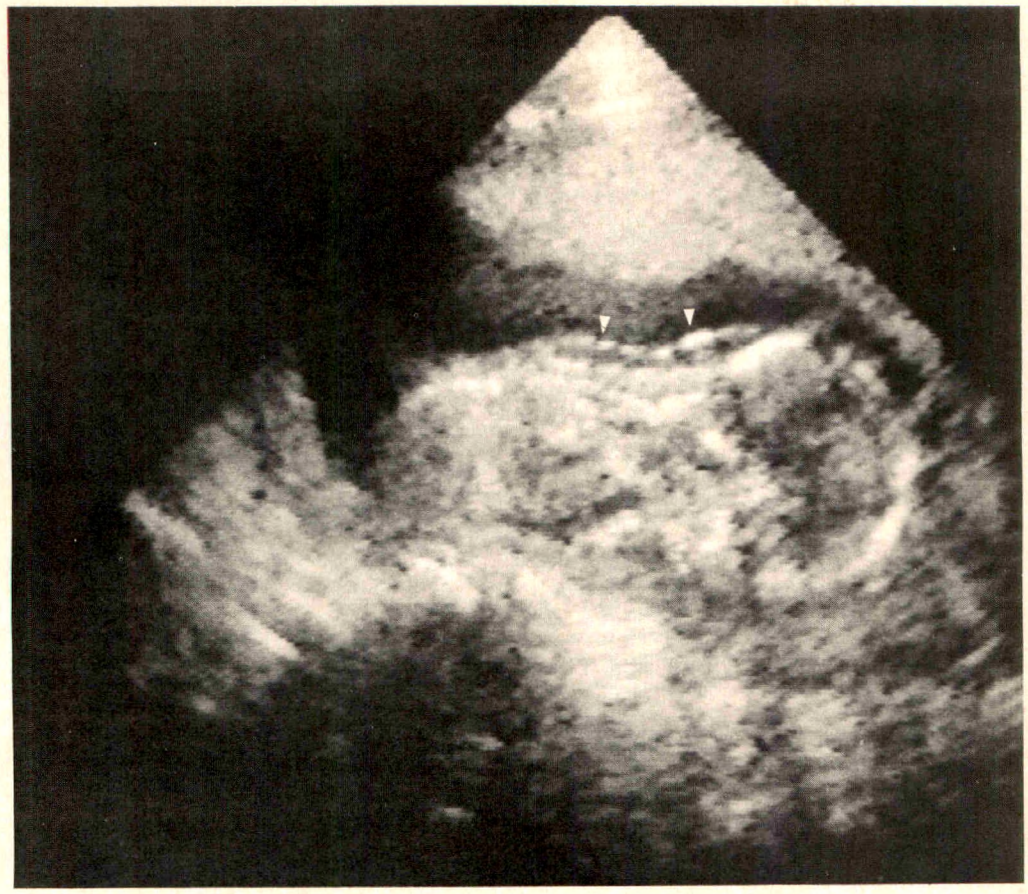

Fig. 2. Nuchal thickening in the dorsal midsagittal plane. *Arrows* point to skin line. Hypoechoic area represents areolar edema.

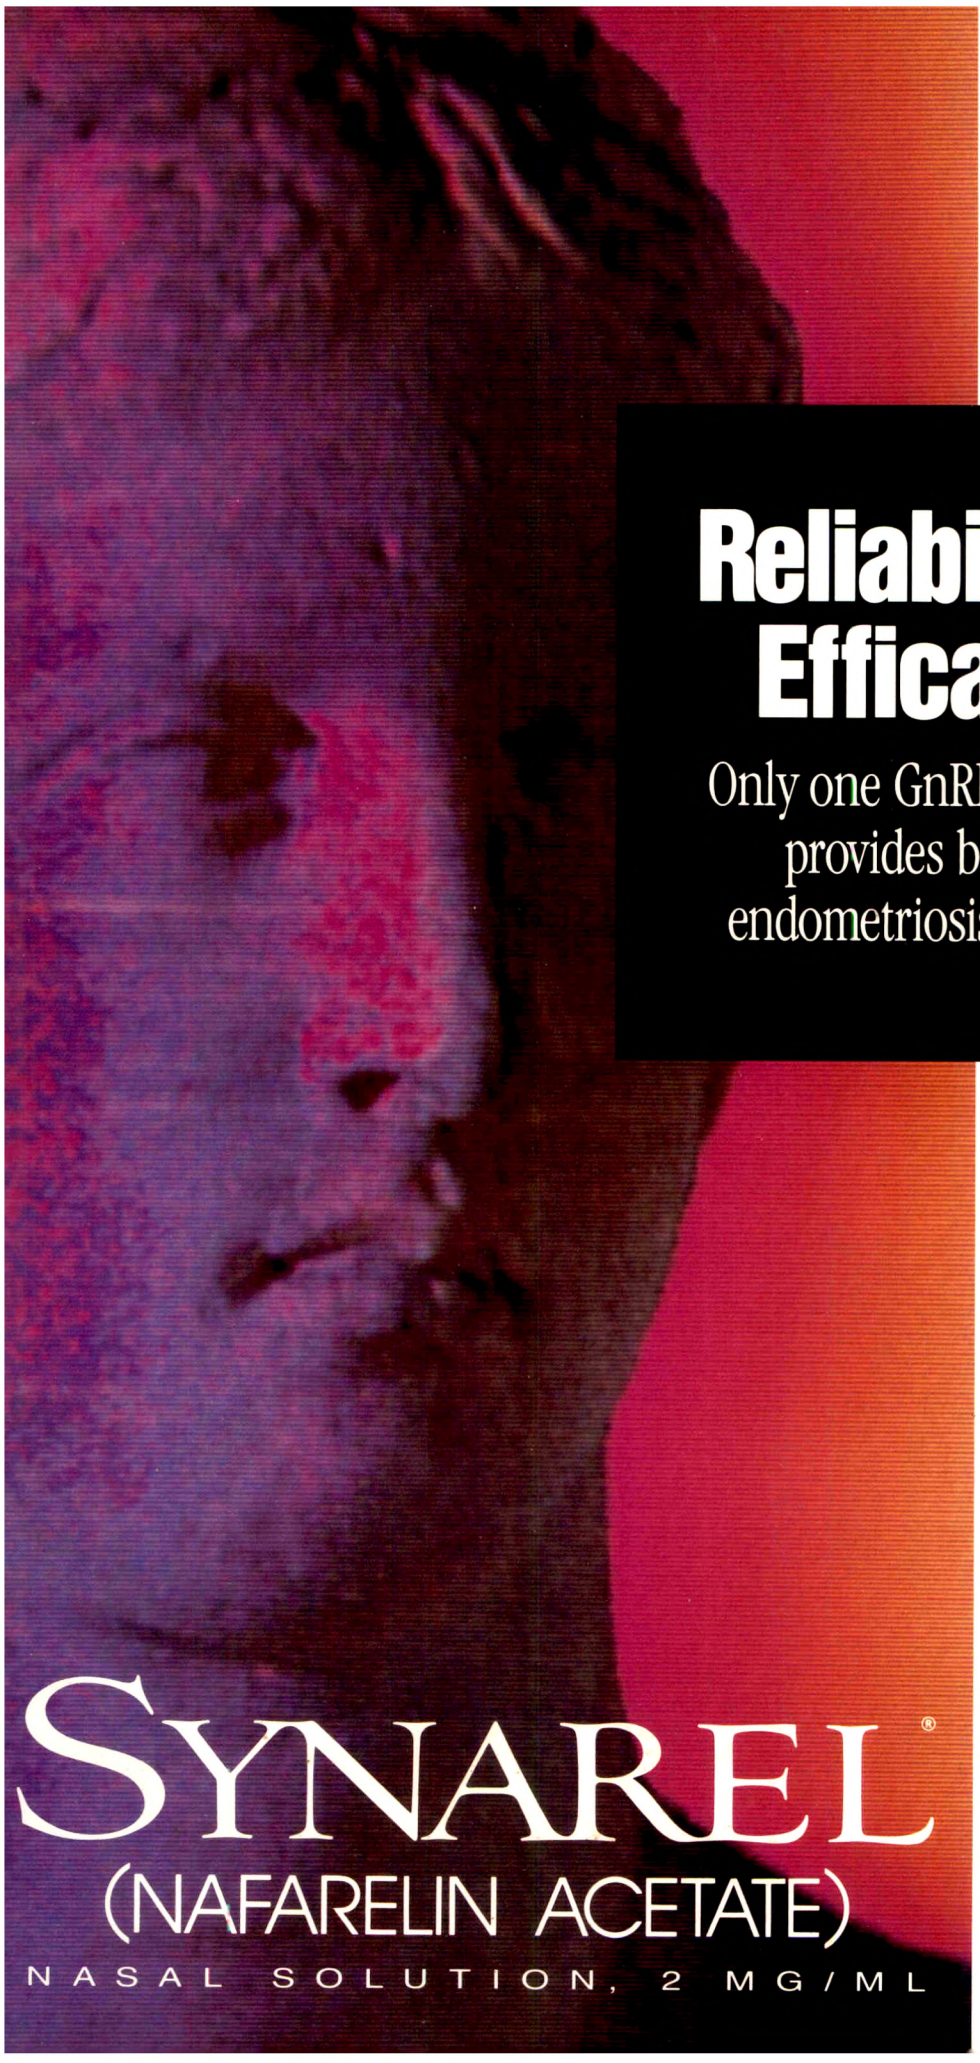
the measured thickening was actually present, the fetus was examined in the dorsal midsagittal plane (Fig. 2). When the angle of the transducer was caudal to a line drawn from the lower margin of the orbit to the auricular point and extended to the center of the occipital bone (Reid's baseline), this plane ruled out any false-positive findings. The fetus, when viewed in the dorsal midsagittal plane with high-resolution ultrasonographic equipment, usually demonstrated a double line in the region of the nuchal thickening. This skin line was a hypoechoic stripe that represented edematous areolar tissue; below this the muscles of the neck were seen. This hypoechoic area added to the thickening in the nuchal region. With the head in normal flexion, the skin bulges at the occiput even if the double line cannot be seen in the dorsal midsagittal plane.

It has been suggested that all pregnant women be screened during the second trimester for trisomy 21,[8] although caution has been urged in making such a practice widespread.[14]

The positive predictive value of biparietal diameter/femur length ratio and nuchal thickness is an estimate of the probability that a fetus identified by these ultrasonic measurements as having a high risk of trisomy 21 or 18 actually is aneuploid for one of these chromosomes. The general population incidence for trisomy 21 and 18 at term is 1 per 1000 and 1 per 7407, respectively, whereas the fetal loss rate between the second trimester and term is 29% and 67%, respectively.[15, 16] The resulting positive predictive value in this study would be 1/47. Thus 46 amniocenteses on chromosomally normal gestations would be necessary for each diagnosis of either trisomy 18 or 21. Amniocentesis currently is performed for advanced maternal age when the risk of a live-born infant with trisomy 21 is 1/385[15] and for a low maternal serum AFP value when the risk of a second-trimester gestation with trisomy 21 is 1 per 250.[17] Therefore about one eighth to one third as many amniocenteses generated from ultrasonographic screening evaluations are required to detect either trisomy 18 or 21 compared with advanced maternal age and low maternal serum AFP level. Ultrasonography is noninvasive and widely available in the United States; such screening would not require extensive technical training or the use of overly expensive ultrasonographic equipment. Finally, we estimate that



a program of ultrasonographic screening and follow-up amniocentesis in a low-risk population would cost approximately $150,000 to detect one case of trisomy 18 or 21, or about $100,000 less than the cost per case when amniocentesis is performed for advanced maternal age or low maternal serum AFP level.

If the approach described in this article were to be widely applied, it might be possible to considerably reduce the number of undiagnosed trisomies before delivery. This approach may be particularly helpful in cases with a low maternal serum AFP level to decide the most appropriate management plan.

Prospective ascertainment of trisomies 18 and 21 now appears warranted to determine if ultrasonographic evaluation would effectively predict chromosomally abnormal gestations in low-risk populations. The possibility that trisomy 13 gestations might also be identified by ultrasonographic assessment of biparietal diameter/femur length ratio and nuchal thickness should likewise be investigated.

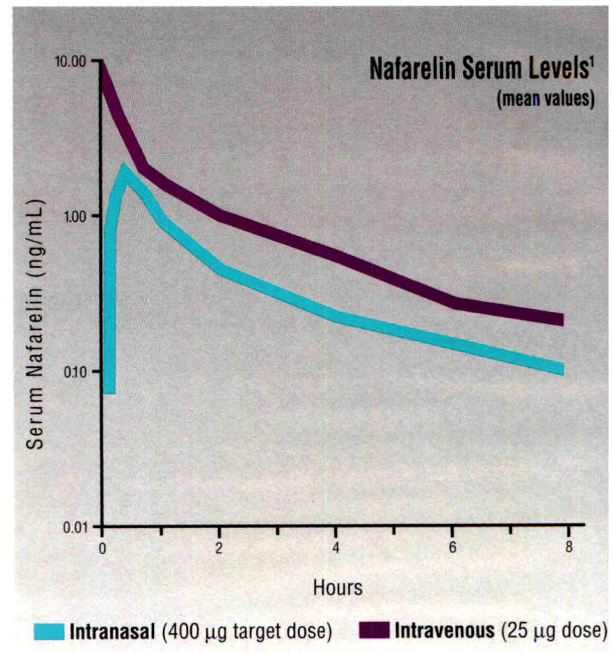
Reliability & Efficacy:

Only one GnRH* agonist provides both in endometriosis therapy

SYNAREL®

(NAFARELIN ACETATE)

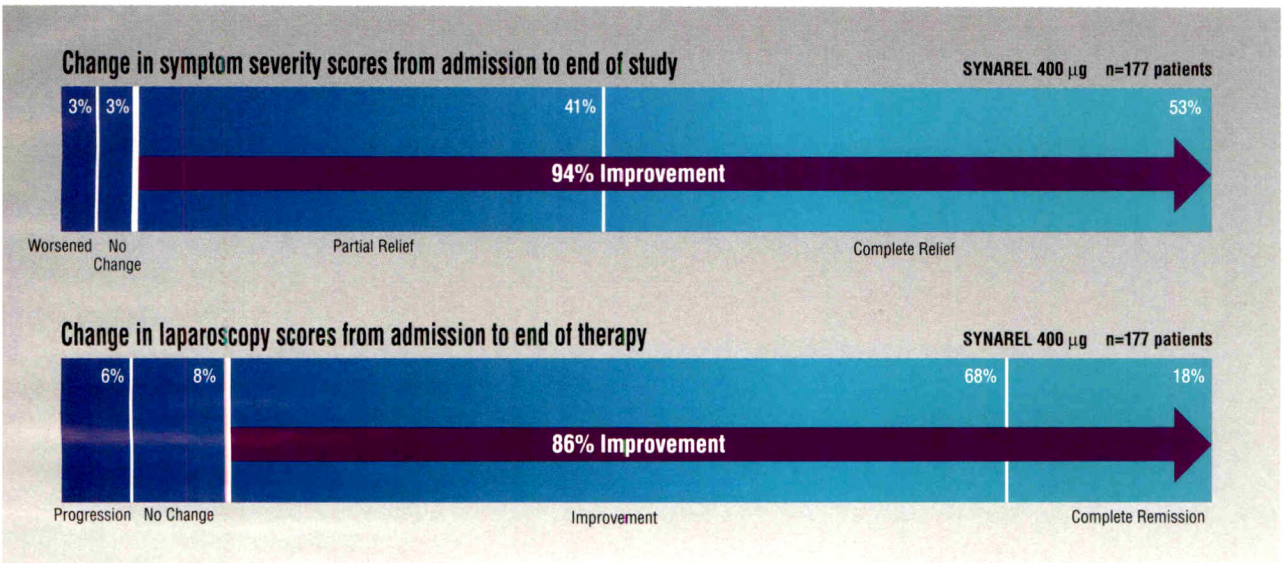


NASAL SOLUTION, 2 MG/ML

*Gonadotropin-releasing hormone analog.
Please see brief summary of prescribing information on last page.

The Only GnRH* Agonist That Satisfies The Needs Of Endometriosis Therapy

Reliable Dosing Control



B.I.D. controlled-dose administration offers unique clinical benefits:

- Controlled intranasal administration
- Highly accurate metered-dose intranasal delivery
- Proven absorption through nasal mucosa
- Well tolerated, with a low incidence of nasal irritation (10%)

Intranasal administration produces nafarelin serum levels comparable to I.V. dosing

- In pharmacokinetic studies, SYNAREL wa rapidly absorbed into systemic circulatior following intranasal administration
- Maximum serum concentrations were achieved between 10 and 40 minutes with intranasal administration.[1]

Outstanding Efficacy In The Management Of Endometriosis, An Estrogen-Dependent Disease

94% of Synarel patients reported improvement of symptoms

- Proven to relieve dysmenorrhea, dyspareunia, and pelvic pain
- Efficacy sustained in 83% of patients at six months posttreatment
- Pregnancy should be ruled out before therapy with SYNAREL is initiated. Patients should be advised to use a nonhormonal method of contraception when taking SYNAREL.

86% of Synarel patients showed improvement of endometriotic lesions

- Improvement in all stages of endometriosis confirmed by post-laparoscopy scores†
- Retreatment cannot be recommended since safety data for retreatment are not currently available

SYNAREL®

NASAL SOLUTION, 2 MG/ML

Endometriosis therapy breakthrough

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chlorid glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and olde treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undia nosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL ma cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patien becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women wh are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pre nancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contr ception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal co traception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnar during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient shoul notify her physician if regular menstruation persists. Patients missing successive doses may experience breakthroug bleeding.

2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or ar allergic to any of its ingredients.

3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should b used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consu her physician.

4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritatio occurred in about 10% of patients.

5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of thi loss may not be reversible. During one six-month treatment period, this should not be important. In patients with majc risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history c osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNARE may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatmer with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content.

6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topic nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decreas the possibility of reducing drug absorption.

7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetat is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound t plasma proteins at 4°C; therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. No mal function is usually restored 4-8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitar gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may b misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats an mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dos respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes c administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonge periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidenc of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There wa an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treate groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there wa a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose female No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive t hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potenti

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment wa discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rat throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on th relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/8 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 60 µg/kg/day and 0.18 µg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administratio throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fet weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted i human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determine SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. I controlled studies comparing SYNAREL (400 µg/day) and danazol (600 or 800 mg/day), the following adverse rea tions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19% 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20% myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8% 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depressio (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticari asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be po sibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mas measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, con pared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bon density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mas measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebra mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if an decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than th recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause adc tional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twic the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and level returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 µg/day and 2% on danazol had tota cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had pos treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8 mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment value were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of th patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) com pared with 4.3% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fraction (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients o SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patient SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

SYNTEX

SYNTEX LABORATORIES, INC
PALO ALTO, CA 94304

WE HAVE A POINT TO MAKE.

SO LITTLE CAN DO SO MUCH.

The Smart Start

OVCON® 35

(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets

Ovcon® 35 offers your patients contraception, with the lowest norethindrone dose of any combination OC. Low incidence of both androgenic side effects[1] and breakthrough bleeding.[2]

Ovcon 35 has a unique estrogen/progestogen ratio. And remember—Ovcon 35 has no generic equivalent.

Amazing how so little can do so much. Our point. Exactly.

OVCON® 35

(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets

Indications and Usage: Ovcon is indicated for the prevention of pregnancy. Some combination products containing 35 mcg or less of ethinyl estradiol report slightly higher pregnancy rates than are reported for the higher dose combination products.

Dose-related Risk of Thromboembolism from Oral Contraceptives: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing 50 mcg or less of estrogen.

Contraindications: Oral contraceptives should not be used in women with any of the following conditions: 1) Thrombophlebitis or thromboembolic disorders. 2) A past history of deep vein thrombophlebitis or thromboembolic disorders. 3) Cerebral vascular or coronary artery disease. 4) Known or suspected carcinoma of the breast. 5) Known or suspected estrogen dependent neoplasia. 6) Undiagnosed abnormal genital bleeding. 7) Known or suspected pregnancy. 8) Benign or malignant liver tumor which developed during the use of oral contraceptive or other estrogen-containing products.

Warnings:

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. Women who use oral contraceptives should be strongly advised not to smoke. Use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1) *Thromboembolic Disorders and Other Vascular Problems.* An increased risk of thromboembolic and thrombotic disease associated with use of oral contraceptives is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. In a study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater. An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported. Studies conducted in the United Kingdom found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction compared to nonusers who do not smoke. Oral contraceptive users who smoke have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. The amount of smoking is a very important factor. British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. The relative risk of thromboembolic disease associated with progestin-only oral contraceptives has not been determined. Cases of thromboembolic disease have been reported in women using progestin-only products, and they should not be presumed to be risk-free. The overall excess mortality rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34, 5/100,000; ages 35-44, 33/100,000; ages 45-49 140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. The highest risk was found in heavy cigarette smokers (15 or more cigarettes per day) who used oral contraceptives and were age 40 or older. Women who smoke should be advised not to use oral contraceptives. The use of oral contraceptives in women over age 40 with other risk factors is not recommended. The mortality associated with all of the methods of birth control is low compared to the risk of childbirth, with the exception of oral contraceptive users who smoke and are over age 40. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and for myocardial infarction is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately.If feasible, oral contraceptives should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. (2) *Ocular Lesions.* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue the medication if there is unexplained sudden or gradual, partial or complete loss of vision; sudden onset of proptosis or diplopia; papilledemia; or retinal vascular lesions, and institute appropriate diagnostic and therapeutic measures. 3) *Carcinoma.* Long term administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. In humans, one study investigated the first 21 cases of endometrial adenocarcinoma in women on oral contraceptives reported to a registry. Of those women without predisposing risk factors for this disease, nearly all occurred in women who had used a sequential oral contraceptive. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestin-only oral contraceptives. No increase in breast cancer in women taking oral contraceptives has been reported although one study reported an increased risk of breast cancer in subgroups of women treated using oral contraceptives with documented benign breast disease. There is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives. 4) *Hepatic Adenoma.* Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study reported a higher risk associated with oral contraceptive formulations with high hormonal potency. Although benign and rare, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short term as well as long term users of oral contraceptives. Two studies relate the risk with duration of contraceptive use, the risk being much greater after 4 or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5) *Use In Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring.* Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy. It has been shown that females exposed in utero to diethylstibestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. A high percentage of such exposed women (30% to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Similar data are not available with the use of other estrogens but it cannot be presumed that they would not induce similar changes. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications and there is no evidence from well-controlled studies that progestins are effective for these uses. Increases in chromosomal aberrations have been reported in women who become pregnant soon after ceasing oral contraceptive therapy. Embryos with these anomalies are virtually always spontaneously aborted. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed the patient should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation should be discussed in light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months. Administration of progestin-only or progestin-estrogen combinations to induce withdrawal bleeding should not be used as a test for pregnancy. 6) *Gallbladder Disease.* Studies have reported an increased risk of surgically confirmed gallbladder disease appearing after one year of oral contraceptive use and doubling of the risk after 4 or 5 years of use. 7) *Carbohydrate and Lipid Metabolic Effects.* A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. Increased serum levels of triglycerides and total phospholipids have been observed in oral contraceptive users. The clinical significance of this observation is unknown at this time. 8) *Elevated Blood Pressure.* An increase in blood pressure has been reported in women receiving oral contraceptives. The prevalence of hypertension in oral contraceptive users may be no higher than nonusers in the first year of oral contraceptive use but increases with longer exposure and in the fifth year of use is two and one-half to three times the reported prevalence in the first year. Women who previously had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. 9) *Headaches.* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of oral contraceptives and investigation of the cause. 10) *Bleeding Irregularities.* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. (11) *Ectopic Pregnancy.* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in oral contraceptive failures, the ratio of ectopic to intrauterine pregnancies is higher than in women not using oral contraceptives since the drugs are more effective in preventing intrauterine rather than ectopic pregnancy. The higher ectopic-intrauterine ratio has been reported with both combination products and progestin-only oral contraceptives. 12) *Breast-Feeding.* A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

Precautions: 1) A complete medical and family history should be taken prior to the initiation of oral contraceptives. Examination should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than 1 year without another physical examination being performed. 2) Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3) Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 4) Because oral contraceptives may cause some degree of fluid retention, conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, cardiac or renal insufficiency or asthma require careful observation. 5) Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6) Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7) Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8) Serum folate levels may be depressed by oral contraceptive therapy. This may complicate subsequent pregnancy with regard to folate deficiency. 9) The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10) Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norephinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein -bound iodine (PBI), T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG, free T_4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. 11) The active yellow tablets and the inert green tablets in the 28 day regimen of Ovcon-35 contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Information for the Patient: Detailed Patient Labeling has been prepared for use by the patient and has been made available for distribution by the pharmacist.

Drug Interactions: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Adverse Reactions: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **Warnings**): Thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis; benign hepatomas; neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle (other reactions, as a general rule, are seen much less frequently or only occasionally); gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes (tenderness, enlargement, and secretion); change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; changes in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, hemolytic uremic syndrome, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erhythema nodosum, hemorrhagic eruption, vaginitis, porphyria.

Acute Overdosage: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Second-trimester ultrasonography: Determinants of visualization of fetal anatomic structures

Val Catanzarite, MD, PhD,[a] and J. Gerald Quirk, MD, PhD[b]
San Diego, California, and Little Rock, Arkansas

Little information has been published regarding rates of visualization of fetal anatomic structures or factors affecting visualization in unselected patients. We prospectively studied these points by scoring visualization of intracranial, spinal, cardiac, ventral wall, umbilical cord, stomach, bladder, and genital anatomy in 573 consecutive midtrimester scans in which no fetal anomalies were seen. Each feature was scored 0, 1, or 2, corresponding to poor, adequate, or optimal visualization, and these eight numbers were summed for an overall visualization score. Overall visualization fell abruptly beyond maternal weight 165 pounds ($p < 0.001$) and rose with advancing gestational age ($p < 0.001$). Placental location did not significantly influence visualization. Overall, an adequate screening scan, defined as adequate visualization of central nervous system, heart, stomach, ventral wall, bladder, and cord was obtained in 51% of scans, and optimal visualization of each of these in only 9% of cases. Factors that might improve anatomic visualization and the implications of these results for the use of ultrasonography in screening for congenital anomalies are discussed. (AAM J OBSTET GYNECOL 1990;163:1191-5.)

Key words: Second trimester, ultrasonography, fetal anatomy, fetal anomalies

The past decade has witnessed a veritable revolution in ultrasonographic technology, recognition of fetal anatomic abnormalities, and the application of ultrasonography to obstetric practice. In the past ultrasonographic examinations were performed primarily for evaluation of gestational age, fetal growth, amniotic fluid volume, and placental location[1, 2]; screening for anatomic defects was a secondary goal. With the current generation of abdominal ultrasonographic equipment, the fetal cortex and ventricles, cerebellum, choroid plexus, spine, stomach, kidneys, and heart can be clearly imaged during the early second trimester; for many fetal organs, not only visualization but also normal size ranges have been reported from 12 to 16 weeks' gestation onward. Second-trimester ultrasonography is now often performed as a screen for congenital anomalies,[3-5] and various views of the fetus have been advocated for incorporation into routine "screening" scans.[6, 7]

Most of the published literature addresses the issue of how early fetus structures can be seen with ultrasonography under ideal conditions rather than how often these structures are adequately visualized in practice. To address this issue we prospectively studied visualization of anatomic features of the fetus during second-trimester ultrasonography by two experienced examiners. In addition to defining frequencies of visualization, we tested the following specific hypotheses:

1. Anatomic visualization improves with advancing gestational age and decreases with increasing maternal weight and abdominal wall fat thickness.
2. Visualization is decreased in the presence of an anterior placenta.
3. Visualization of caudal structures is worse when the fetus is in breech presentation, and visualization of rostral structures is worse when the fetus is in vertex presentation.

Subjects and methods

The study population was drawn from patients who had second-trimester, transabdominal level II examinations performed by one of us in our genetics-ultrasound unit between July 1, 1988, and March 31, 1989. Patients were excluded if they were referred because of identified or suspected fetal anomalies, if the amniotic fluid volume was abnormally increased or reduced, or if fetal anomalies were identified during the scan.

All examinations were performed using an ATL/ADR Ultramark-4 ultrasound machine (Advanced Technology Laboratories, Bothell, Wash.) equipped with 5 MHz linear, 5 MHz annular, and 3 MHz linear and sector transducers. Examination began with recording of fetal number, lie, and presenta-

Table I. Scoring of anatomic visualization

Intracranial anatomy
1. Cranial outline, orbits, midline echo (falx), and cerebellum
2. Ventricles and/or choroid plexus, facial architecture including maxilla and mandible

Spine
1. Ossification centers in normal anatomic relationship in transverse view at each level from occiput to sacrum and in longitudinal view
2. Intact overlaying skin at each level

Heart
1. Four chambers visualized in transverse view; equal atrial and ventricular size
2. Equal wall thickness and intact interventricular septum

Ventral wall
1. Unobstructed longitudinal or transverse view of umbilical insertion
2. Unobstructed longitudinal and transverse views; normal width in both views

Stomach
1. Echolucent area below heart, of appropriate size, in left side of fetal abdomen
2. Echogenic inner wall of stomach seen

Bladder
1. Echolucent area midline, below umbilical insertion, of appropriate size
2. Echogenic inner wall of bladder seen

Umbilical cord
1. Interrupted echoes showing two arteries and vein in longitudinal or transverse view
2. Complete outlines of circular vein and arteries in transverse view or of "spiral rope" appearance in longitudinal view

Genitalia

Male
1. Echodense phallus at an acute angle to the anterior abdominal wall; fetal thighs adducted
2. Distinct outline of fetal penis and/or scrotum

Female
1. Thighs adducted, with clitoral echo seen
2. Distinct outline of "triple-U" configuration of clitoris and labia

tion, cardiac and limb activity, amniotic fluid volume, and placental location. The following measurements were performed: biparietal diameter, head circumference, cerebellum, abdominal circumference, and femur length.

Fetal anatomic structures were scored 0, 1, or 2 according to the visualization criteria of Table I. The sum of these eight scores was used as an overall visualization score (range, 0 to 16). For purposes of data analysis, we described an "adequate" screening examination as one in which the visualization score for each of the seven scores excluding genitalia was at least 1, and an "optimal" screening examination as one in which each of these seven scores was 2.

In addition we recorded time for ultrasonography, maternal height and weight, and measured the abdominal wall thickness from skin to the rectus sheath.

Gestational age was inferred from menstrual dates. If the menstrual dates were uncertain, or differed from ultrasonographic determination by more than 10 days before 22 weeks' gestation, or by more than 14 days at 22 to 26 weeks' gestation, ultrasonographic dating was used.

Table II. Summary of maternal characteristics and selected ultrasonographic observations

	Mean	*SD*	*Range*
Time (min)	17.3	5.6	10-30
Height (in)	64.7	2.6	57-73
Weight (lbs)	154.3	32.3	99-347
Skin to rectus (mm)	19.3	8.3	4-56
Gestational age (wk)	17.9	2.7	13-27
Breech (%)	39.1		
Vertex (%)	43.4		
Anterior placenta (%)	48.0		

Statistical analysis was performed with the STATSOFT 2.1 program (Statsoft, Inc., Tulsa). We used the t test for comparison of independent samples and for determining significance of correlation values, and the F test for significance of multiple regression (R^2) values.

Results

During the study period 589 level II ultrasonographic scans in patients without previously identified anomalies were performed. Leading indications were maternal age (56%), low maternal serum α-fetoprotein (AFP) (20%), elevated maternal serum AFP (13%), and a family history of congenital anomalies (9%).

Sixteen patients were excluded from analysis because of ultrasonographically detected anomalies as follows: neural tube defects (four cases), cystic hygroma (two), isolated two-vessel cord (two), holoprosencephaly and omphalocele (one), holoprosencephaly and oligohydramnios (one), nonimmune hydrops alone (two) or with ventricular septal defect (one), osteogenesis imperfecta (one), multicystic dysplastic kidney with contraleteral renal agenesis (one), and chroid plexus cyst (one).

The remaining 573 patients with normal ultrasonographic findings were the basis for this study. The mean gestational age was 17.9 ± 2.7 weeks; maternal weight ranged from 99 to 347 pounds (mean 154 ± 32 pounds), and the time spent scanning averaged 17 ± 6 minutes. Selected measured parameters are summarized in Table II.

Of the 573 patients, 433 underwent amniocentesis. In four cases trisomy was identified despite normal ultrasonography; three cases of trisomy 21 and one case of trisomy 18 were detected. In no case was a neural tube or abdominal wall defect missed by ultrasonography.

The effects of maternal weight on visualization are summarized in Table III. The overall visualization

score decreased significantly with maternal weight: $r = -0.48$ ($p < 0.0001$). There was a dramatic drop in visualization beyond the 70th percentile in weight: the mean visualization score fell from 11.5 ± 3.0 at <70th percentile (165 pounds) to 9.3 ± 3.7 at the 70th to 90th percentile (165 to 198 pounds) ($p < 0.001$), and to 6.2 ± 3.9 at >90th percentile weight (>198 pounds) ($p < 0.0001$).

Visualization improved with advancing gestational age for the overall score: $r = .34$, $p < 0.001$. Scores for each anatomic feature also improved with gestational age; r values ranged from 0.10 and 0.12 for ventral wall and stomach, respectively, to 0.27 for spine and genitalia and 0.34 for umbilical cord. Each of these was significant at $p < 0.005$. The improvement with gestational age is illustrated for each anatomic feature in Fig. 1.

Visualization of intracranial anatomy by these criteria plateaued at approximately 30% for adequate visualization and 70% for optimal visualization at 19 to 20 weeks' gestation or after. The high rate of inadequate visualization before 15 weeks are largely a result of poor visualization of the cerebellum. After 15 weeks the cerebellum could almost always be seen when the midline structures and orbits were well visualized.

Ossification centers of the spine were visualized in >90% of cases from 15 weeks onward; however, visualization of intact overlying skin continued to improve until 19 to 20 weeks.

All four chambers of the heart could be seen after 16 to 17 weeks in >75% of cases, but demonstration of equal chamber size and wall thickness and an intact septum rose to plateau at 21 to 26 weeks, at only 50%.

The cord insertion could be visualized throughout this gestational age range, but optimal clarity improved with gestational age. There were insufficient numbers for analysis, but there appeared to be a decline in visualization beyond 23 to 24 weeks, because of a relative decline in amniotic fluid volume in relation to fetal size.

The stomach and bladder were both seen in most cases throughout the second trimester; however, for each gestational age group, there was a 5% to 10% rate of nonvisualization of the stomach and a 10% rate for the bladder over the scan duration. A distinct echogenic lining of the stomach was seen in >80% of cases beyond 19 weeks and of the bladder in >90% of cases beyond 19 weeks. Visualization of cord vessels rose throughout the second trimester.

Visualization of the genitalia plateaued at approximately 80% after 20 weeks, and optimal visualization was approximately 60% after 22 weeks.

Multiple regression analysis was performed to determine the effects of measured and inferred parameters on overall visualization. Maternal height, placental position, and fetal lie and presentation did not significantly influence visualization. Maternal weight, skin-to-rectus distance, and gestational age were significant; the combination of weight and gestational age predicted visualization with $R^2 = 0.39$ ($p < 0.0001$, F test). The inclusion of other parameters did not substantially improve the regression fit.

Table III. Visualization by weight percentile

Weight percentile	*Maternal weight (lbs)*	*Visualization score (mean ± SD)*
<10th	<120	12 ± 2.9
10th-20th	120-127	12.6 ± 2.6
20th-30th	127-135	11.6 ± 2.7
30th-40th	135-142	11.9 ± 2.7
40th-50th	142-149	11.3 ± 2.9
50th-60th	149-157	11 ± 2.9
60th-70th	157-165	10.3 ± 3.4
70th-80th	165-177	9.5 ± 3.4
80th-90th	177-198	9.1 ± 3.9
>90th	198-349	6.2 ± 3.9

$p < 0.001$, Weight <70th percentile versus weight 70th to 90th percentile;

$p < 0.001$, Weight 70th to 90th percentile versus weight >90th percentile.

We also analyzed the frequency of "adequate" and "optimal" screening examinations by maternal weight and gestational age. Among patients who weighed <165 pounds (<70th percentile), 13% of patients had "optimal" and 56% had "adequate" screening examinations. Corresponding figures for the 165- to 198-pound group (70th to 90th percentile) were 9% and 34%, and for the >198-pound group (>90th percentile) were 2% and 17%. Breakdown by gestational age is shown in Table IV.

The influence of fetal presentation (vertex vs breech) on visualization of caudal and rostal structures showed a slight but significant improvement in visualization of intracranial anatomy with the fetus in breech presentation (score 1.56 ± 0.60 vs 1.45 ± 0.70, $p = 0.03$); there were no differences in visualization of genitalia or bladder attributable to position.

Comment

We are aware of only one previous study of the rates of visualization of fetal organs in an unselected population undergoing second-trimester ultrasonography. Zador et al.[8] reported results for examinations by ultrasonographers scanning with 3.5 MHz linear and sector transducers. Their criteria for organ visualization differed from ours; however, for each of five organs with comparable criteria—heart, spine, stomach, bladder, and umbilical cord—the rates of visualization reported in our study are higher. These differences may be attributable to ultrasonographer experience or to the use of higher resolution equipment (5 MHz transducers) in our study.

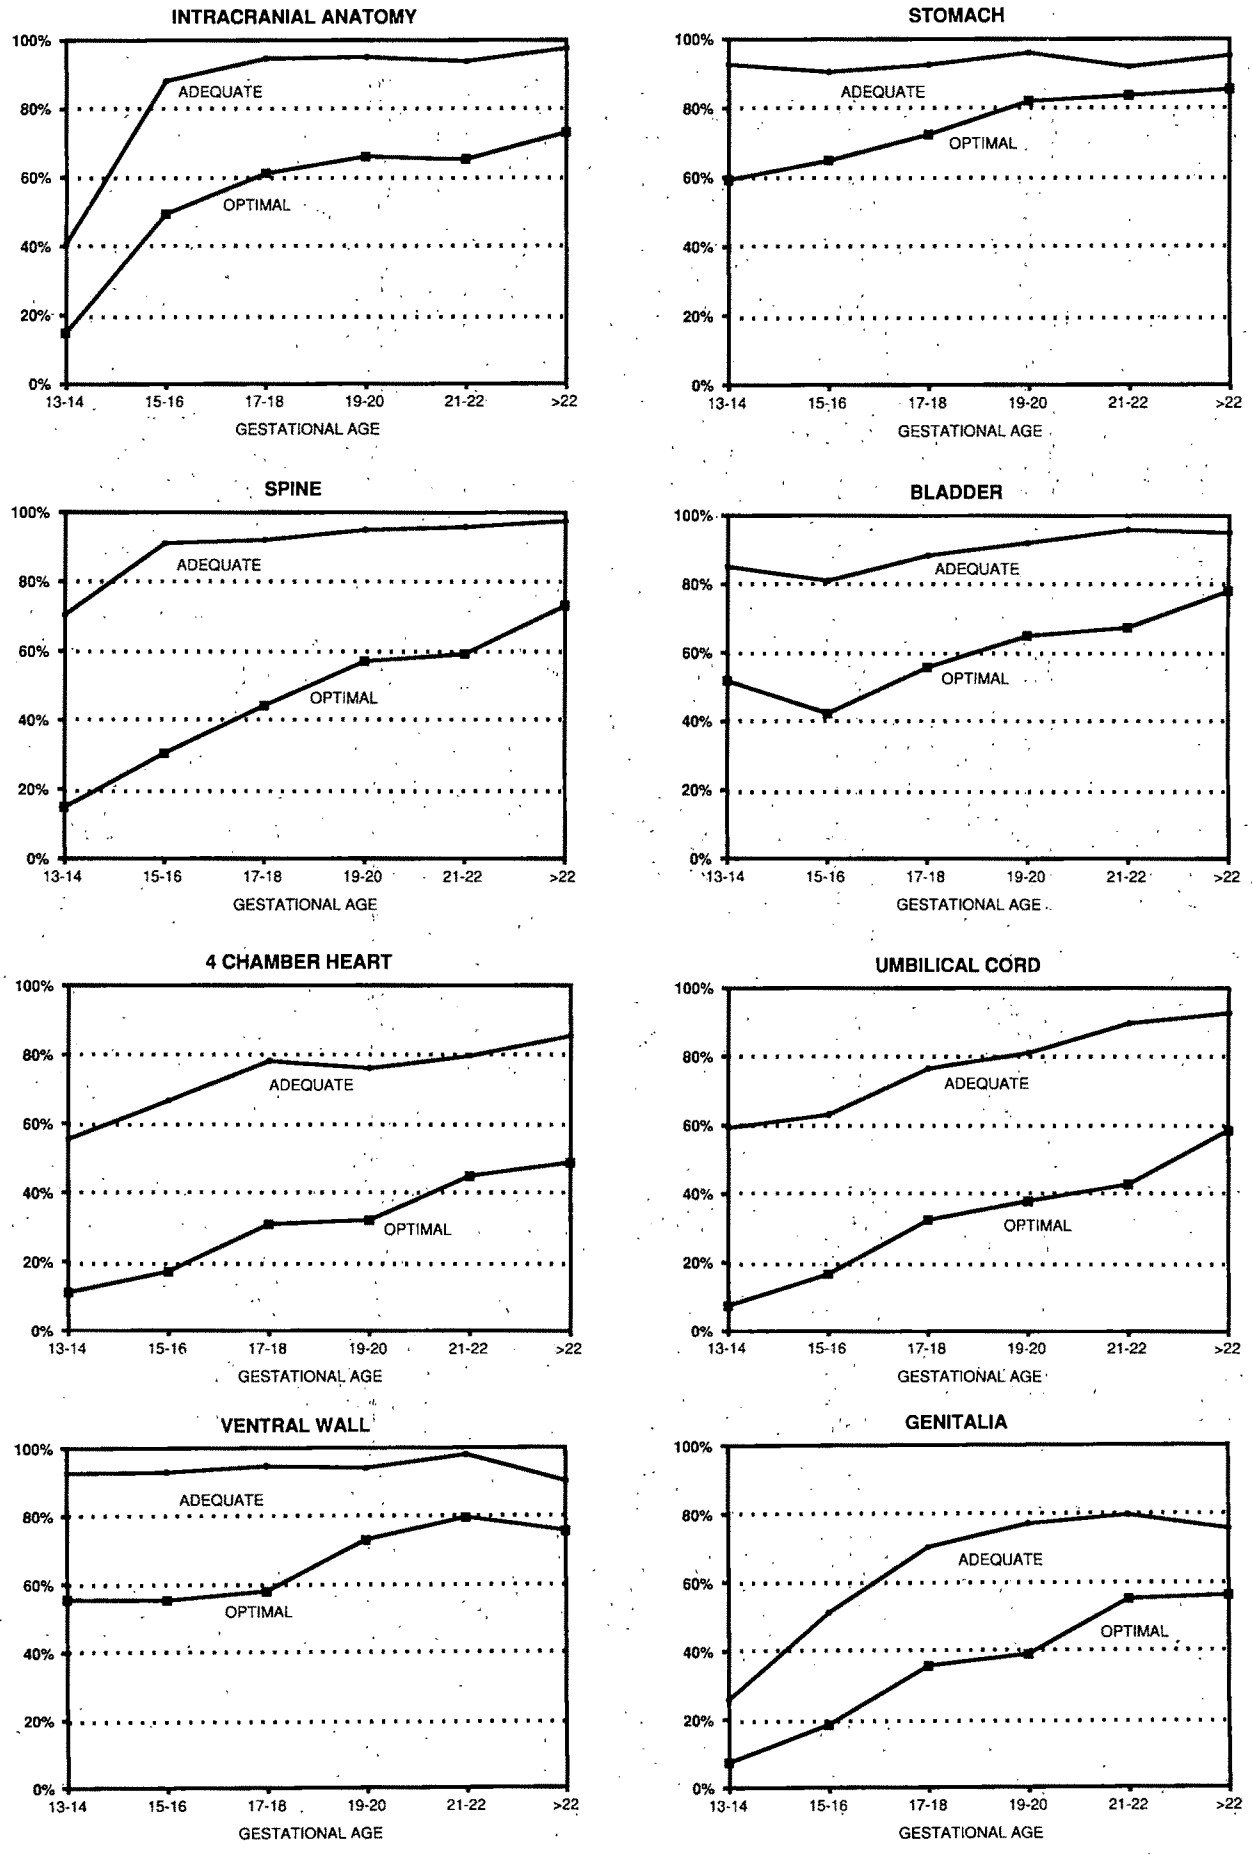

Fig. 1. Anatomic visualization versus gestational age.

Several results of our investigation were unexpected. The rate of "adequate" visualization of the fetal heart was substantially lower than anticipated. With our equipment a view that showed all four chambers was demonstrated in only 80% of patients after 17 weeks' gestation, and visualization adequate as screening for cardiac defects was obtained in <40% of patients at 15 to 20 weeks, and in slightly over half of patients at or beyond 21 weeks. By our criteria "adequate" anatomic screening was accomplished in only 56% of cases overall, and in 221 of 456 (46%) patients at 15 to 20 weeks, when most of our screening scans for congenital anomalies are performed.

The rates of visualization might be improved in any of several ways. The duration of examination would probably increase the visualization rates for at least three points of anatomy—stomach, bladder, and cardiac anatomy. Equipment could be upgraded; the Ultramark-4 with transducers as described is a relatively inexpensive but commonly used machine. Our informal in-house comparisons suggest that image quality is better for several more expensive units (eg, Ultramark-5, Acuson-128). Combined transabdominal and transvaginal scanning would undoubtedly improve visualization rates when anatomy of the head or the fetal rump is obscured by position with the maternal pelvis. Finally, given the same equipment and same time frame, more experienced ultrasonographers might be able to better demonstrate fetal anatomic structures. However, changes in scan duration, ultrasonographic equipment, or ultrasonographic experience are alterations that could not currently be made within the logistic and financial constraints of our ultrasonographic laboratory.

These data have important implications for any ultrasonographic laboratory. The "visualization" scores can be used to compare current ultrasonographic machines with other units. In addition, we now have objective information regarding the frequency of "adequate" and "optimal" screening examinations that may have important medicolegal implications[9] and are of use in counseling patients on the limitations of ultrasonography in our hands.

Finally, our practice has been to perform level II, screening ultrasonograms at 15 to 20 weeks' gestation in the belief that this represented a compromise between optimal fetal anatomic visualization and a time in pregnancy at which termination would still be acceptable to our patients, should an abnormality be found. For patients in the higher weight ranges, and particularly those weighing >90th percentile (198 pounds), the visualization scores and the rates of adequate screening ultrasonography were quite low. Our impression, based on limited numbers of cases at present, is that visualization scores of 8 to 12 are routinely obtained with transvaginal ultrasonography at 12 to 14 weeks. We suspect that transvaginal ultrasonography, at least for the obese patient, will prove to be a superior technique for screening than transabdominal ultrasonography at any time during the second trimester; we plan a prospective comparison to test this hypothesis.

Table IV. Numbers of cases with adequate (score = 1 or 2) and optimal (score = 2) visualization of intracranial, spinal, cardiac, ventral wall, stomach, bladder, and umbilical cord anatomy

Gestational age (wk)	*No.*	*All scores of 1 or 2*	*All scores of 2*
13	5	0 (0%)	0 (0%)

Infertility and eating disorders

Donna E. Stewart, MD, G. Erlick Robinson, MD, David S. Goldbloom, MD, and Charlene Wright, BSc

Toronto, Ontario, Canada

Sixty-six consecutive infertility clinic patients were prospectively screened with the 26-item Eating Attitudes Test and a study questionnaire. Women identified as being at high risk for an eating disorder were then interviewed to confirm or refute the diagnosis. A total of 7.6% of infertility clinic women were found to suffer from anorexia nervosa or bulimia nervosa. If eating disorders not otherwise specified were included, a total of 16.7% of infertility patients were found to suffer from an eating disorder. Among infertile women with amenorrhea or oligomenorrhea 58% had eating disorders. Because women often fail to disclose eating disorders to their gynecologists and may appear to be of normal weight, it is recommended that a nutritional and eating disorder history be taken in infertility patients, particulary those with menstrual abnormalities. It has previously been shown that disordered eating and nutrition can affect menstruation, fertility, maternal weight gain, and fetal well-being. (Am J Obstet Gynecol 1990;163:1196-9.)

Key words: Infertility, eating disorder, anorexia nervosa, bulimia nervosa

Anorexia nervosa, characterized by self-imposed starvation as a result of a relentless pursuit of thinness and a fear of fatness, occurs in a serious form in about 1% of young adult and adolescent women.[1] A related disorder, bulimia nervosa, is defined as episodic patterns of binge eating followed by a variety of methods to counteract the caloric ingestion, including vomiting, starvation, and laxative abuse; bulimia is also accompanied by an intense preoccupation with weight and shape. This may occur in the context of anorexia nervosa or more commonly as a separate syndrome at an actuarially normal body weight. The prevalence of bulimia nervosa as defined by DSM-III-R criteria[2] is 1.7% of adolescent and young adult women.[3] Milder variants of anorexia nervosa and bulimia nervosa that fail to meet criteria for a specific eating disorder, defined by DSM-III-R as eating disorders not otherwise specified, occur in a further 3% to 5% of the female population.[4,5] Eating disorders not otherwise specified is characterized by (1) a person of average weight who does not have binge eating episodes but frequently engages in self-induced vomiting for fear of gaining weight, (2) all of the features of anorexia nervosa in a female subject except absence of menses, or (3) all of the features of bulimia nervosa except the frequency of binge eating episodes.[2] A careful survey of women aged 16 to 35 attending a family practice found a total prevalence of eating disorders and partial syndrome (eating disorders not otherwise specified) of 4%.[5] Eating disorders result in significant morbidity related to episodes of weight loss, vomiting, electrolyte disturbance, gastrointestinal problems, psychiatric sequelae, and reproductive complications.[1] Although it is known that many of these patients, particularly those with anorexia nervosa, have primary or secondary amenorrhea and are infertile,[6] the reproductive aspects of anorexia nervosa and bulimia nervosa have been inadequately studied.

Two early studies examined menstruation, fertility, and pregnancy in patients previously diagnosed as having anorexia nervosa.[7,8] Starkey and Lee[7] found that most anorexic patients reported weight gain, return of menses, and fertility with successful treatment, but women without weight gain did not experience menstrual return or conception. Hart et al.[8] described three women with anorexia nervosa who were induced to ovulate with human menopausal gonadotropin–human chorionic gonadotropin but then experienced significant fetal loss because of miscarriages, multiple pregnancies, premature births, and low birth weights.

Investigators have also previously found that some women with amenorrhea or infertility who are seen by gynecologists actually have undisclosed eating disorders.[9-13] An early study by Fries[13] found a high proportion of women with an eating disorder among 30 women with secondary amenorrhea associated with weight loss. Nillius[11] reported that 34% of amenorrheic women in his study were found to have amenorrhea caused by self-induced weight loss. The diagnosis of

6/1/22461

such underlying problems may be hampered by the fact that some bulimic women appear to be of normal weight by actuarial or population mean standards. However, longitudinal weight history may reveal premorbid obesity that led to highly restrictive dieting coupled with bulimic behavior.[14] A recent Australian study using the Eating Disorders Inventory also found elevated drive for thinness and interoceptive awareness subscales to point toward disordered eating in 30 infertility clinic patients,[15] but these investigators did not conduct confirmatory interviews for eating disorders. Bates et al.[12] found that 47 women with unexplained infertility and menstrual dysfunction were practicing weight control by caloric restriction to maintain a fashionable body habitus. The report did not state whether formal eating disorders were found in any woman in this study. When 36 of these women followed a dietary regimen designed to increase their weight to predicted ideal body weight, menstruation resumed in most, with subsequent spontaneous conception. It is of interest that 97% of these infertile women and their husbands had been evaluated previously for infertility with a variety of diagnostic gynecologic studies without weight loss being identified as the cause of the infertility.

The aim of the present study was to ascertain prospectively the prevalence of eating disorders (anorexia nervosa, bulimia nervosa, and eating disorders not otherwise specified) in a group of women with infertility attending a university reproductive biology service.

Material and methods

Consecutive women with infertility seen at a university reproductive biology service were assessed by means of a standardized, reliable, valid self-report measure, the 26-item Eating Attitudes Test (EAT-26), which is presently in widespread use as a screening instrument for eating disorders.[16] The EAT-26 focuses on specific dysfunctional beliefs and behaviors associated with anorexia nervosa and bulimia nervosa.[16] The women also completed a study questionnaire on current and past weights, menstrual history, and gynecologic history. All women identified on screening tests as having possible eating disorders (EAT-26 score ≥ 20) or who reported a past or current eating disorder were interviewed by one of the investigators (D. E. S.) to confirm or refute the diagnosis of an eating disorder by DSM-III-R criteria. Statistical analyses were performed by one-way analysis of variance.

Results

Sixty-six women completed the EAT-26 and the study questionnaire. There were three refusals to complete these questionnaires, resulting in a 96% response rate. One woman who refused later acknowledged to infertility clinic staff that she had been treated in the past for bulimia nervosa and was still regularly binge eating and inducing vomiting. The three women who refused to complete the questionnaires are not included in the data.

The mean age of the women completing the questionnaires was 30.4 years (range 21 to 39). Their mean weight was 103% ideal body weight (range 72% to 143%). Ideal body weight was defined as the average weight for a given height and age, determined from statistics compiled in 1979 by the Association of Life Insurance Medical Directors of America and Society of Actuaries. Twelve women had abnormal menses (amenorrhea or oligomenorrhea).

According to the cutoff score described above for the EAT-26, 12 women were identified as possible cases of eating disorders. In addition, two women who did not meet the criteria disclosed on the study questionnaire that they were being treated for an eating disorder and one woman who scored zero on all EAT-26 items was identified by a note on her questionnaire saying "I am *not* bulimic" and an allegation of bulimia made by her sister. Clinical interviews with all 15 women confirmed that 11 had an eating disorder. Utilizing DSM-III-R criteria, four women had bulimia nervosa, one had anorexia nervosa, and six had eating disorders not otherwise specified. This results in a prevalence of a formal specific eating disorder (anorexia nervosa or bulimia nervosa) of 7.6% (16.7% when eating disorders not otherwise specified are included). The four women identified as possible cases on screening but not confirmed by interview were all overweight (ideal body weight = 120%), dieting, and preoccupied by food. Of the 12 women in the total sample with abnormal menses, seven (58.3%) suffered from anorexia nervosa, bulimia, or eating disorders not otherwise specified (Table I).

There was no significant difference in the percent ideal body weight between women with eating disorders and women without eating disorders. Analysis of variance was used to compare scores of amenorrheic and oligomenorrheic women with those of women with normal menses. Total scores on EAT-26 were significantly higher ($p < 0.0001$) in the abnormal menses group than in the normal menses group. Although all four amenorrheic women had significantly lower percent ideal body weight than all other women ($p = 0.04$), the percent ideal body weight was not significantly different between normal and the total abnormal menses group.

Comment

We found a 7.6% prevalence by DSM-III-R criteria of a specific eating disorder (anorexia nervosa or bulimia nervosa) in consecutive women seen in a university hospital clinic for infertility. This rate is two to four

Table I. Menses and eating disorder in 66 infertility clinic women

Eating disorder	*Menses*			*Total*
	Normal	*Oligomenorrhea*	*Amenorrhea*	
Anorexia nervosa	0	0	1	1
Bulimia nervosa	0	2	2	4
Eating disorder not otherwise specified	4	2	0	6
No eating disorder	50	4	1	55
TOTAL	54	8	4	66

times that predicted by population and general practice studies of women in this age group.[1, 3, 5] The 12 women with menstrual abnormalities in our sample had a higher prevalence (58%) of eating disorders than normally cycling women (7%), suggesting that infertile women with menstrual abnormalities are at even higher risk of suffering from an eating disorder. Other investigators have described the endocrine findings associated with menstrual cycle abnormalities in women with anorexia nervosa and bulimia nervosa. In general, these women tend to have fewer luteining hormone secretory spikes and a trend toward lower mean 24-hour luteinizing hormone levels than controls.[16] Stimulation with gonadotropin-releasing hormone produced elevated luteinizing hormone responses in the bulimic group and blunted luteinizing hormone responses in the anorexic group.[16] Estradiol levels were uniformly lower in women with anorexia nervosa,[17] and stimulation with estradiol revealed diminished luteinizing augmentative responses and a trend toward diminished follicle-stimulating hormone augmentative responses in patients with anorexia nervosa and bulimia nervosa as compared with those of controls.[16] Other studies have shown that approximately 50% of normal weight women with bulimia nervosa have menstrual abnormalities with impaired follicular maturation caused by impaired gonadotropin secretion.[17, 18] Moreover, it has been shown in normal young women of normal body weight who diet for 6 weeks (800 to 1000 kcal/day) that a variety of changes in endocrinologic function develop with actual disruption of menstrual cycles for 3 to 6 months after dieting in approximately 20%.[19] Recently investigators have shown that women with eating disorders not otherwise specified also frequently have menstrual dysfunction.[21] If women with eating disorders not otherwise specified are included in our prevalence figures for an eating disorder in infertility clinic patients, the rate rises to 16.7%, a finding of concern that warrants further study. Eating disorders may play an important etiologic role in infertility because recent work has shown that 73% of normal infertile patients who were below ideal body weight because of caloric restriction conceived spontaneously when their weight was corrected.[12]

None of the women we identified with eating disorders had divulged this problem to the infertility clinic gynecologist before the introduction of the screening questionnaires. The exposure to these questionnaires appears to have encouraged more open disclosure about eating disorders. Five women wrote notes on their questionnaires stating they were worried that abnormal eating habits had caused their infertility. On psychiatric interview all four women with bulimia nervosa and three of six women with eating disorders not otherwise specified confided that they had previously sought treatment for an eating disorder but failed to report it to the gynecologist. All expressed a concern that they had "damaged" themselves by their disordered eating behaviors but expressed relief at now being able to discuss this further.

Patients often fail to volunteer information about eating disorders to their gynecologists and may sometimes appear to be of normal weight (in fact, percent ideal body weight was a poor predictor of an eating disorder in this and other studies)[5]; therefore, when infertile patients are assessed, especially those with menstrual abnormalities, there is a need for routine careful inquiry into nutritional intake and eating disorder history. Relevant clinical screening inquiries include a history of highest and lowest ever weights, desired body weight, average daily caloric intake, dieting, and alternative attempts at weight control. For routine evaluation, "consciousness raising," or research purposes, screening of infertility clinic patients with the EAT-26 using a cutoff score of ≥ 20 will identify a group of women at high risk for an eating disorder. Given the brevity, ease of scoring, and ability of the EAT-26 to correctly identify 73% of patients with eating disorders in our study, it appears to be a fairly useful screening instrument in this population. Women identified as high risk on screening can then be referred for further assessment to confirm or refute the diagnosis of an eating disorder. Women with false-positive results on the EAT-26 were characteristically overweight dieters, a finding confirmed by other investigators.[22] It should be borne in mind that the EAT-26 will not identify all women with eating disorders, especially those who deny symptoms. However, an awareness of the frequency of

eating disorders in infertility patients followed by careful clinical inquiry should correctly identify most cases.

All women in this study who had a confirmed eating disorder were advised to have psychiatric treatment and nutritional counseling. In clinical practice, women found to have an eating disorder should be treated for this before infertility investigations and treatments are pursued. We have previously shown that women whose eating disorders persist during pregnancy gain less weight, have more complications of pregnancy, have smaller babies with lower 5-minute Apgar scores, experience more difficulties in postpartum adjustment, and have more problems with breast-feeding.[10] It is not known if the high rate of spontaneous conception with correction in weight is applicable to formal eating disorders, but our earlier work indicates that successful treatment of eating disorders reduces morbidity of the pregnant woman and her offspring.[10]

We thank Dr. C. Redmond, Dr. C. Derzko, and Dr. R. Casper for encouraging their infertility patients to participate in this survey, and Dr. M. Morris for contacting the high-risk women identified by the screening instruments.

Postpartum osteomyelitis caused by group B streptococcus

K. Berkowitz, MD, and R. McCaffrey, MD
New York, New York

Postpartum infections caused by group B streptococci are generally limited in scope. We report a case of vaginal colonization with group B streptococcus that progressed in the postpartum period to osteomyelitis that necessitated total hip replacement. The patient had no risk factors predisposing to streptococcal osteomyelitis. An altered immune status in pregnancy and intrapartum bacteremia may be involved in the pathogenesis of this infection. (Am J Obstet Gynecol 1990;163:1200-1.)

Key words: Colonization, osteomyelitis, group B streptococcus

Postpartum infections associated with vaginal group B streptococcal colonization are commonly limited to adjacent anatomic structures such as the uterus and bladder. Transmission of the organism to the newborn has been associated with a variety of neonatal complications including sepsis and osteomyelitis.[1] We report an unusual complication of group B streptococcal infection in a woman in whom severe postpartum osteomyelitis developed and required hip replacement.

Case report

A 34-year-old nulligravid woman was seen at term in active labor. Her medical history was unremarkable. She had conceived with clomiphene therapy. The antepartum course had been uneventful. The membranes ruptured spontaneously 24 hours before delivery without any signs of chorioamnionitis. The vaginal delivery was uncomplicated and a partial third-degree episiotomy was repaired easily. A routine intrapartum culture for group B streptococcus was noted to be positive after delivery. The patient had no evidence of infection and was not treated. The infant had no signs of streptococcal disease. The patient complained of pain at the episiotomy site on the third postpartum day. The site was clean, she was afebrile, and her discomfort resolved with analgesia. She remained afebrile on the fourth postpartum day but complained of pain in the left hip and buttock. Physical examination revealed no limitation of motion in the left hip. There were no signs of deep vein thrombosis. Hip radiographs were normal. Her symptoms resolved with analgesia. She was discharged on the fifth postpartum day.

At home the patient experienced increasing left hip pain radiating to the left buttock and knee that was not relieved by analgesics. She was unable to raise her left leg by the seventh postpartum day and was readmitted for evaluation. Neurologic examination revealed no motor or sensory deficits. Venogram of the lower extremities and tomographic scans of the lumbar-sacral spine and pelvis were unremarkable. Pelvic ultrasonogram showed no evidence of hematoma. The patient became febrile to 39.0° C with an associated elevation in white blood cell count to 20,000 cells/mm^3 and sedimentation rate of 145. A three-phase bone scan revealed synovitis of the left hip. Hip joint aspiration yielded clear sterile fluid. Empiric antibiotic therapy with cefazolin and tobramycin was initiated on the fourteenth postpartum day when hip radiographs showed narrowing of the left hip joint and demineralization of the acetabulum. A second hip joint aspirate grew group B streptococcus on the fifteenth postpartum day. A synovial biopsy showed purulent granulation tissue and grew group B streptococcus. Cultures were negative for mycotic disease or acid-fast bacilli. Rheumatoid factor and antinuclear antibody determinations were negative. The patient improved after initiation of high-dose parenteral penicillin G and minidose heparin therapy. She was discharged on the thirtieth postpartum day to begin rehabilitative therapy. Serial hip radiographs showed progressive deterioration of the hip joint. A bone scan performed 6 months postpartum revealed avascular necrosis of the left acetabulum. She then underwent low-friction arthroplastic total hip replacement with a Charnley prosthesis.

Comment

Septic arthritis and osteomyelitis caused by group B streptococcal infection is seen infrequently in neonates and children. It is very rare in adults but has been reported in patients with diabetes mellitus or altered immune status.[2] Colonization reservoirs and opsonic antibody-complement abnormalities may be involved in the pathogenesis of this infection.[2] Postpartum osteomyelitis caused by group B streptococcus has not previously been reported. The potential for group B streptococcal colonization to progress to a disseminated infection such as postpartum osteomyelitis is documented

in this case report. It can be postulated that hematogenous spread of the organism to the hip was facilitated by bacteremia accompanying the process of labor and delivery. The patient's altered immune status of pregnancy may have increased her susceptibility to the development of infection.

Disseminated postpartum infections require a concerted diagnostic effort aimed at identifying the reservoir responsible for bacterial seeding. Organisms found in antenatal or intrapartum vaginal cultures are likely sources of infection. Information gained from vaginal cultures may help the clinician to initiate definitive rather than empiric therapy in women with unclear causes for severe postpartum infections.

Antenatal spontaneous perforation of the extrahepatic biliary tree

Syam Chilukuri, MD, Virgilio Bonet, MD, and Mason Cobb, MD
East Lansing, Michigan

Spontaneous perforation of the biliary system is an unusual neonatal phenomenon that is rarely recognized at birth. To date, it has not been reported antenatally. A 16-year-old pregnant adolescent had an ultrasonogram at 25 weeks of pregnancy that revealed ascites in the fetus. After the infant was delivered at 32 weeks, a hepato-iminodiacetic acid scan showed a spontaneous rupture of the common bile duct. The infant was treated with external drainage of the biliary tree and recovered well. This case demonstrates that spontaneous perforations of the bile ducts can occur much earlier than the usually described 2 to 12 weeks after birth, can be diagnosed antenatally, and should be added to the list of causes of fetal ascites. (Am J Obstet Gynecol 1990;163:1201-2.)

Key words: Fetal ascites, spontaneous perforation of bile duct

Spontaneous perforation of the common bile duct is uncommon in neonates but has been well documented as the second most common surgical cause of jaundice in the newborn.[1] However, it has not been reported to have occurred in utero, with most cases occurring between 2 and 12 weeks after birth.[1] This case illustrates fetal ascites diagnosed before birth, which subsequently was shown to be antenatal perforation of the common bile duct.

Case report

A 16-year-old white adolescent (gravida 1, para 0, abortions 0) was progressing normally until approximately 25 weeks of gestation when the fetus was found to have developed ascites on a routine ultrasonogram. The mother was not found to have polyhydramnios but preeclampsia subsequently developed and the infant girl was delivered via cesarean section at 32 weeks' gestation.

The infant was delivered without incident; Apgar scores were 7 and 9, birth weight was 1940 gm, and head circumference was 30 cm. The infant was thus normal size for 32 weeks of gestation. She was not jaundiced. The abdomen was distended but there was no organomegaly. An ultrasonogram revealed no abnormality except the ascites.

Liver enzyme levels were normal. A hepato-iminodiacetic acid scan was obtained and extravasation of the radionuclide from the extrahepatic biliary tree established the diagnosis of a spontaneously perforated duct.

The infant's abdomen was explored 2 days after birth when she was found to have 150 to 200 ml of free bile in the peritoneal cavity. An operative cholecystogram showed flow into the duodenum but no extravasation. External drainage of the biliary tree was performed via a cholecystostomy. The postoperative course was un-

eventful except for a single reaccumulation of ascites that was tapped and was found to be chylous. A repeat hepato-iminodiacetic acid scan before discharge was normal. The infant remains healthy and is thriving at 18 months' follow-up.

Comment

Spontaneous perforation of the extrahepatic biliary ducts should be added to the list of causes of fetal ascites. Among the known causes of fetal ascites are urinary tract abnormalities, gastrointestinal diseases, biliary atresia, storage diseases, malignancies, Rh or ABO incompatibility leading to isoimmunization, and other causes of fetal hydrops.[1,2]

Although the cause is still not known, the location of the spontaneous perforation is usually at the junction of the cystic duct and the common hepatic duct.[1] This finding suggests a tendency for developmental errors at this site. The theory advanced by Lilly et al.[1] is that the perforation is a result of a localized embryonic mural malformation in this area. The same area is also the most frequent site of choledochal cyst, which further supports this thesis.

The common period of discovery is between 4 and 12 weeks of age, although it is occasionally seen at birth. The pathognomonic finding is biliary ascites, but a definitive preoperative diagnosis can be made by an intravenous hepatocholangiogram with technetium 99m-Tc disofenin or other isotopes of technetium 99m-Tc, such as hepato-iminodiacetic acid.

Treatment is surgical and can be accomplished with external drainage.[1] A cholecystostomy may be added as in this case. Other internal drainage procedures have also been advocated by some authors but are not well accepted.

Antenatal diagnosis has advanced clinical acumen in recognizing and treating many congenital surgical disorders. To date, antenatal spontaneous perforation of the extrahepatic bile ducts has not been reported.[1,2]

This case also reveals that bile duct perforation can occur at least as early as the twenty-fifth gestational week. Previously this was thought to occur after birth, although the defect itself is congenital.[1]

Extrahepatic bile duct perforation should be considered in the differential diagnosis of fetal ascites. A surgical consultation with the mother and family and plans for postnatal surgical care are indicated in such cases.

Antenatal diagnosis of molybdenum cofactor deficiency

R. George F. Gray, PhD,[a] Anne Green, MSc,[a] Shishta Nadda Basu, MRCOG,[b] Glyn Constantine, MD,[b] Roy G. Condie, MD,[b] Claude Dorche, PhD,[c] Christine Vianey-Liaud, PhD,[c] and Pierre Desjacques, PhD[c]

Analysis of uncultured chorionic villus material from a woman at risk of fetus with sulfite oxidase deficiency revealed a deficiency of sulfite oxidase. This was confirmed on termination of the pregnancy. (AM J OBSTET GYNECOL 1990;163:1203-4.)

Key words: Molybdenum cofactor deficiency, chorionic villus sampling, amniocentesis

Molybdenum cofactor deficiency is a rare autosomal recessive disorder that, in the neonate, appears with fits, choreiform movements, and lens dislocation. Biochemically it is characterized by a deficiency of sulfite and xanthine oxidases and the accumulation in the body fluids of sulfite, thiosulfate, S-sulfocysteine, xanthine, and hypoxanthine. We report a further case with details of a successful antenatal diagnosis by chorionic villus sampling and amniocentesis.

Case history

The index case was the fourth pregnancy of a Pakistani Moslem couple who were first cousins. There had been delivery of a healthy male, a female who died of pneumonia at age 1 month, and a spontaneous miscarriage. The pregnancy was uneventful and a female was born (birth weight, 3.75 kg) at term. Apgar scores at birth were 9 and 10 at 1 and 5 minutes, respectively. However, the infant ate poorly and underwent an apnea attack at 10 hours, with generalized convulsions and opisthotonos. An electroencephalogram revealed epileptogenic abnormalities, suggesting a progressive encephalopathy. A computerized axial tomography scan of the brain revealed areas of low attenuation with slight ventricular dilation. Intermittent convulsions continued, ventricular tachycardia developed and she died on day 12 after birth. Plasma uric acid was substantially reduced (<1 mmol/L), whereas urinary xanthine (433 mmol/mmol creatinine) and hypoxanthine (10 mmol/mmol creatinine) were raised. Unfortunately insufficient samples were available for the measurement of sulfur-containing metabolites and cultured fibroblasts were not available. The clinical picture and the abnormal purine metabolites led us to the presumptive diagnosis of molybdenum cofactor deficiency.

Antenatal diagnosis

The mother was first seen with her fifth pregnancy at 6 weeks' gestation. A chorionic villus sample was taken transcervically at 11 weeks' gestation. The uncultured chorionic villus tissue revealed a total deficiency of sulfite oxidase, whereas hexosaminidase activity was present. However, because of transportation problems between the laboratories in Birmingham and Lyon, the specimen was in transit for 3 days. Inasmuch as it was not known how stable the enzyme was under these condition, an amniocentesis was carried out at 16 weeks' gestation. The amniotic fluid supernatant revealed increased concentrations of S-sulfocysteine (22 μmol/L, normal values (<1) and a low concentration of cysteine (15 μmol/L, 2 SD, normal range 72 to 134). The amniotic fluid supernatant uric acid concentration was normal (165 μmol/L, normal range 95 to 202). An extraamniotic termination of pregnancy was carried out at 17 weeks' gestation. The cultured amniotic fluid cells and abortus fibroblasts revealed a gross deficiency of sulfite oxidase activity, whereas the abortus liver revealed no detectable sulfite and xanthine oxidase activity. A postmortem examination revealed no histologic abnormalities in any tissues on light or electron microscopy.

Comment

The assay of sulfite oxidase in uncultured chorionic villus material permits a diagnosis of molybdenum cofactor deficiency within 7 days of sampling, whereas analysis of purine and sulfur-containing metabolites in the amniotic fluid gives a more rapid result than the

enzyme assay on cultured amniotic fluid cells. Amniotic fluid uric acid concentrations are clearly not useful diagnostically.

We thank Bill Mackenzie of Marston Green Hospital, Birmingham, England, for carrying out the chorionic villus sampling, Dr. Anne Aukett of Dudley Road Hospital for her help with the index case, and Kevin Carpenter of the Sheffield Children's Hospital for the purine metabolite assays.

Preoperative evaluation of serum CA 125, TAG 72, and CA 15-3 in patients with endometrial carcinoma

John T. Soper, MD,[a] Andrew Berchuck, MD,[a] George J. Olt, MD,[a] Andrew P. Soisson, MD,[a] Daniel L. Clarke-Pearson, MD,[a] and Robert C. Bast, Jr., MD[b]

Durham, North Carolina

We evaluated 109 women with endometrial carcinoma to determine the accuracy of preoperative tumor-associated antigen levels (CA 125, CA 72, CA 15-3) for prediction of extrauterine disease and whether TAG 72, CA 15-3, or both would improve the predictive value of CA 125 alone. Eleven (12%) of 80 patients with disease confined to the uterus or positive cytologic findings had CA 125 values >35 U/ml versus 12 (65%) of 20 patients with extrauterine metastasis. Therefore CA 125 values had sensitivity of 65% and specificity of 88%. The TAG 72 level was elevated (>6 U/ml) in 4% of patients with localized disease and 30% with metastasis. CA 15-3 was elevated (> 30 U/ml) in 17% and 65% in these categories, respectively. TAG 72 or CA 15-3 levels did not improve the combination of sensitivity and specificity of CA 125 alone. In addition, only one of 10 patients with microscopic metastasis (three cases) or positive peritoneal cytology (seven) had elevation of any of these tumor-associated antigen levels. Failure to detect occult metastasis and a high false-positive rate limit the role of these tumor-associated antigen assays in the preoperative evaluation of patients with endometrial carcinoma. (Am J Obstet Gynecol 1990;163:1204-9.)

Key words: Endometrial cancer, tumor-associated antigens, CA 125, TAG 72, CA 15-3

It has been established that women with early clinical stage endometrial carcinoma frequently have extrauterine metastasis detected only through staging laparotomy. The International Federation of Gynecology and Obstetrics (FIGO) recently designated a surgical staging system for endometrial cancer.[1] Although the risk of extrauterine metastasis can be predicted on the basis of several pathologic features,[2] only histologic grade and depth of the uterine cavity are known preoperatively in the majority of women with endometrial cancer. The development of a sensitive and specific noninvasive test that could be applied preoperatively to predict the presence of extrauterine metastasis would allow selection of patients at high risk for extrauterine disease who would most likely benefit from comprehensive surgical staging procedures, including selective pelvic and paraaortic lymphadenectomy.

Niloff et al.[3] first reported the association of elevated CA 125 levels with advanced and recurrent endometrial carcinomas. Recent reports by Duk et al.[4] and Patsner et al.[5] suggested that preoperative elevations of serum CA 125 levels might identify women with clinically early endometrial carcinomas who have occult metastatic disease. Berchuck et al.[6] subsequently reported that increasing expression of CA 125 in the primary endo-

6/1/23001

metrial cancer was associated with increased metastatic potential. On the basis of these reports, we conducted a prospective evaluation of preoperative sera from women with endometrial carcinomas to determine the value of CA 125 elevations in predicting extrauterine metastasis. Levels of two other tumor-associated antigens, TAG 72 and CA 15-3 were also measured to determine whether levels of these tumor-associated antigens in combination with CA 125 would improve the sensitivity or specificity achieved with CA 125 alone.

Material and methods

One hundred nine women with endometrial adenocarcinomas treated between 1986 and 1989 had pretreatment sera available in sufficient quantity to determine levels of CA 125, TAG 72, and CA 15-3. Sera were obtained within 1 week before primary operation or institution of definitive therapy in one patient with clinically advanced disease. All patients underwent preoperative evaluation consisting of physical examination, pelvic examination with the patient under anesthesia, chest x-ray film, and other appropriate radiographic studies. Surgical stage was assigned according to FIGO criteria[1] based on the results of surgicopathologic findings at laparotomy.

In patients with disease grossly confined to the uterus at laparotomy, bilateral selective pelvic and paraaortic lymphadenectomy was performed unless the patient had a grade 1 or 2 lesion confined to the endometrium or invading the inner myometrium by frozen section of the hysterectomy specimen. Peritoneal washings for cytologic testing and omental biopsy were performed in all patients. One woman with clinical evidence of systemic and vaginal metastasis was treated without laparotomy. Ten patients with gross intraperitoneal carcinomatosis underwent hysterectomy, bilateral salpingo-oophorectomy, and tumor debulking without lymph node sampling.

Preoperative sera were separated, frozen, and stored at −70° C. Tumor-associated antigen assays were performed after completion of initial operation and clinicians were blinded to the results of the assays.

CA 125 assay. An immunoradiometric assay (Centocor, Malvern, Pa.) was performed as previously described[7, 8] to quantitate CA 125 levels in 100 μl portions of serum. All assays were performed in duplicate and were compared with a normal curve constructed by use of control samples with known quantities of CA 125 antigen. A value of 35 U/ml was selected as threshold for this study.[7, 8]

Tumor-associated glycoprotein (TAG 72) assay. A solid-phase double-determinant radioimmunometric assay (Centocor) was also used to quantitate serum TAG 72 levels. All assays were performed in duplicate. Polystyrene beads coated with monoclonal antibody B72.3 were incubated simultaneously with 100 μl serum samples combined with 100 μl iodine 125–labeled B72.3.[9-11] Specimens were incubated for 18 hours in a 4° C water bath. The polystyrene beads were washed four times with 5 ml distilled water and radioactivity was determined by a gamma scintillation counter. Standard curves were constructed with known quantities of TAG 72 from a standard source. A level of 6 U/ml was assigned as a threshold for this study.

Serum CA 15-3 assay. The serum CA 15-3 assay was also a solid-phase double-determinant immunoradiometric assay (Centocor). Polystyrene beads coated with monoclonal antibody 115.D8[12, 13] were incubated with 200 μl of serum for 60 minutes at room temperature. Each well was rinsed three times with a total of 15 ml distilled water. Two hundred microliters of mouse monoclonal antibody DF3 labeled with ^{125}I was added for an additional 60 minutes. The beads were rinsed with 15 ml distilled water and radioactivity was counted in a γ-scintillation counter. A standard curve was obtained with samples that contained known concentrations of CA 15-3. Unknown sera were run in duplicate and the corresponding concentration of CA 15-3 was determined directly from the standard curve. A threshold level of 30 U/ml was assigned for this study.

The χ^2 test was used for analysis of trends with significance declared at the $p < 0.05$ level. Standard definitions[14] of sensitivity, specificity, and predictive values of positive and negative tests were used to determine the ability of tumor-associated antigens to discriminate the presence or absence of metastatic disease.

Results

Pretherapy sera were obtained from 109 women with endometrial carcinoma before surgical staging or therapy. Ninety-seven patients (89%) had disease clinically localized to the uterus and cervix preoperatively, whereas 12 (11%) had advanced clinical stage disease (Table I). Elevations of CA 125 and CA 15-3 levels correlated with advanced clinical stage: 82% of patients with advanced disease had elevations of these tumor-associated antigen levels versus 11 and 14%, respectively, for patients with clinically localized disease ($p < 0.05$). Serum TAG 72 elevations were observed in 8% of patients with clinical stage I disease but only 36% of those with advanced disease (Table I). Elevations of CA 125 and CA 15-3 levels also were associated with advanced FIGO surgical stage ($p < 0.05$, Table I). However, elevated levels of these tumor-associated antigens were detected in 14% and 17% of 89 patients with disease histologically and cytologically confined to the uterus. Three of 33 patients with disease confined to the uterus who did not undergo lymph node sampling had elevated CA 125 levels; one had no residual

Table II. Serum tumor-associated antigen elevations versus myometrial invasion and histologic grade: Disease confined to uterus and cervix

	No.*	CA 125 >35 U/ml (%)	TAG 72 >6 U/ml (%)	CA 15-3 >30 U/ml (%)
Myometrial invasion				
None	21	2 (10)	1 (5)	3 (14)
Inner third	40	5 (13)	2 (5)	7 (18)
Middle third	12	1 (9)	0	3 (27)
Outer third	16	3 (19)	1 (6)	2 (13)
Histologic grade				
1	35	3 (9)	2 (6)	4 (11)
2	38	5 (14)	1 (3)	9 (24)
3	16	3 (19)	1 (6)	2 (13)

*Includes seven patients with malignant peritoneal cytologic test results (stage IIIA).

invasive cancer in the hysterectomy specimen and the other two had inner myometrial invasion only.

The 89 patients with disease histologically confined to the uterus and cervix were further analyzed to determine whether extent of myometrial invasion or histologic differentiation correlated with elevation of the tumor-associated antigen levels (Table II). In general, there was not a significant relationship between elevated levels and either of these variables, although there was a trend toward elevated CA 125 levels among patients with deep myometrial invasion or histologic grade 3 lesions (Table II).

Comparison of the surgicopathologic extent of disease with preoperative serum tumor-associated antigen levels is displayed in Table III. Both CA 125 and CA 15-3 levels significantly correlated with surgicopathologic findings ($p < 0.05$, Table III). However, none of the seven patients with positive peritoneal cytologic findings and only one of three with histologically documented occult metastasis had preoperative elevations of any of the tumor-associated antigens (Table III).

The site and histologic grade of metastatic lesions appeared to be related to preoperative CA 125 elevations, although the differences were not statistically significant. Only three (38%) of eight patients with metastasis limited to the retroperitoneal nodes had elevated CA 125 levels versus 10 (91%) of 11 with carcinomatosis or extraabdominal metastasis. Similarly, CA 125 elevations occurred in three (38%) of eight women with grade 3 lesions compared with 10 (83%) of 12 patients with grade 1 or 2 lesions.

Serum TAG 72 and CA 15-3 levels were elevated in four patients with metastatic disease and normal CA 125 levels. However, these tumor-associated antigen levels were normal in nine and five patients, respectively, who had metastatic disease and elevated CA 125 levels. Either the TAG 72 or CA 15-3 levels were elevated in 11 (12%) of 89 with surgically localized disease, whereas four patients (4%) had coordinate elevations of CA 125 and one of the other tumor-associated antigen levels.

Eleven (12%) of 89 patients with disease histologically confined to the uterus and 13 (65%) of 20 with histologic evidence of extrauterine metastasis had elevated CA 125 levels (Table III). Therefore, elevations of serum CA 125 levels had a sensitivity of 65% and specificity of 88% with a positive predictive value of 54% and negative predictive value of 92% for predicting the presence or absence of extrauterine metastasis. The use

Table III. Serum tumor-associated antigen elevations versus extent of extrauterine metastasis

Extent of disease	*No.*	*CA 125* >35 U/ml (%)*	*TAG 72 >6 U/ml (%)*	*CA 15-3* >30 U/ml (%)*
Surgical stage I-II	82	11 (13)	4 (5)	15 (18)
Malignant peritoneal cytologic test results	7	0	0	0
Microscopic metastasis	3	0	1 (33)	0
Gross metastasis (>1 cm)	17	13 (76)	5 (29)	11 (65)

*$p < 0.05$, surgical stage I-II plus malignant cytologic test results versus microscopic plus gross metastasis.

of TAG 72 and CA 15-3 alone (Table III) or use of combinations of tumor-associated antigen levels did not significantly improve on the combined sensitivity and specificity of serum CA 125 alone. Elevations of one or more tumor-associated antigen levels had a sensitivity of 85% but specificity of only 71%, whereas coordinate elevations of CA 125 with either TAG 72 or CA 15-3 had a sensitivity of only 45% with specificity of 96%.

Preoperative clinical evaluation was compared with the surgicopathologic extent of disease and serum CA 125 elevations (Table IV). Although the CA 125 levels were elevated in only 11% of patients with clinically localized disease who were confirmed surgically to have localized disease and 90% of those with clinically advanced disease confirmed to have extrauterine metastasis, the preoperative CA 125 level did not distinguish between those patients with early clinical stage who had clinically occult extrauterine metastasis from those with benign adnexal masses who were found to have disease confined to the uterus on surgicopathologic evaluation (Table IV).

Table IV. Serum CA 125 elevations compared with clinical evaluation and surgical pathologic findings

	Surgical pathologic findings	
Clinical evaluation	*Confined to uterus and/or cervix**	*Extrauterine metastasis*
Localized to uterus and/or cervix	10/87 (11)†	4/10 (40)

*Includes seven patients with malignant peritoneal cytologic results (FIGO stage IIIA).

†CA 125 elevations per total patients (%).

Comment

Recent studies by Duk et al.[4] and Patsner et al.[5] that reported elevation of circulating levels of CA 125 in women with endometrial adenocarcinomas prompted us to evaluate serum levels of tumor-associated antigens in our patient population. Duk et al.[5] found CA 125 elevations in 12 (67%) of 18 patients with surgically documented advanced disease. Patsner et al.[6] performed complete bilateral pelvic and paraaortic lymphadenectomy in all their patients with disease apparently confined to the uterus. They reported that elevation of CA 125 had a sensitivity of 90% and a specificity of 98% for discriminating surgically localized from surgically advanced disease.

Our findings do not support the routine use of preoperative serum CA 125 assays in women with endometrial carcinoma. Serum CA 125 elevations did correlate with clinical stage, surgical stage, and surgicopathologic extent of metastasis. However, we found an unacceptably high false-positive rate among patients with disease histologically confined to the uterus and cervix with a resultant positive predictive value of only 54% for elevations of CA 125 levels. Furthermore, none of those in the small subset of patients with occult extrauterine metastasis or malignant peritoneal cytology had elevations of CA 125. Finally, only 40% of patients with clinically occult but histologically confirmed metastasis had elevations of serum CA 125 levels before operation (Table IV); this is the group most likely to benefit from preoperative serum tumor-associated antigen level determinations.

We noted a false-positive rate of 12% for CA 125 elevations among women with endometrial carconima histologically confined to the uterus and cervix but were not able to demonstrate any difference by histologic grade or depth of myometrial invasion. It is unlikely that false-positive elevations resulted from omitting pelvic and paraaortic lymphadenectomy in 33 of our patients. The three "false-positive" results in this group occurred in patients at very low risk (less than 5%) for extrauterine metastasis.[2] Although the majority of cases of endometrial carcinoma express CA 125,[4,6] the mechanism for entry of the antigen into peripheral circu-

lation is unknown. It is assumed that CA 125 from endometrial lesions is shed into the endometrial cavity and the antigen gains access to the circulation through lymphatic drainage.[4] Elevations of serum CA 125 levels in women with endometrial carcinomas could be a result of both increased expression of CA 125 and breakdown of normal tissue barriers.

Duk et al.[4] suggested that elevated CA 125 levels in patients with early stage disease might identify those at risk for recurrence. This may reflect occult metastasis not detected by routine surgical staging techniques; however, all our study patients underwent upper abdominal exploration including peritoneal cytology and omental biopsy. Our follow-up data are not mature enough to confirm the prognostic importance of initial preoperative CA 125 elevations in patients with disease histologically confined to the uterus, cervix, or both areas.

The identification of elevated serum CA 125 levels in 65% of patients with histologic evidence of metastasis raises the possibility of monitoring CA 125 levels during therapy of those who have no measurable disease after surgical therapy. Duk et al.[4] reported a significant correlation between serial CA 125 levels and the clinical course of endometrial cancer in a small group of patients. Although many reports have confirmed the utility of serial CA 125 levels in monitoring of patients with ovarian carcinoma,[7, 15, 16] the role for monitoring serial CA 125 levels in women with endometrial carcinomas has not be established.

The two other tumor-associated antigen assays selected for this study, TAG 72 and CA 15-3, were chosen on the basis of several attributes. Both antigens are detected by monoclonal antibodies originally generated against membrane-enriched fractions of human breast carcinomas[9-13] but are also expressed by other types of benign and malignant human tissues. Tumor-associated glycoprotein defined by the monoclonal antibody B72.3 is expressed by the majority of carcinomas from a variety of primary sites, including endometrial adenocarcinomas.[10, 11, 17, 18] This antigen is also expressed by benign secretory endometrium.[17, 18] The shed antigen can be detected in the sera of women with malignant pelvic masses.[19] The DF-3 antigen (CA 15-3) is expressed by a variety of malignancies and levels are elevated in the sera of the majority of women with active breast[12] and ovarian carcinomas.[13, 19] Unlike TAG 72, DF-3 is expressed by benign endometrium in all phases of the menstrual cycle.[17] In a study of women with pelvic masses, we found that the use of these assays in conjunction with CA 125 assays improved the specificity for discriminating between benign and malignant masses compared with CA 125 alone.[18]

In this study CA 15-3 elevations correlated with clinical and surgicopathologic advanced endometrial carcinomas but had a higher false-positive rate than CA 125 levels. The TAG 72 assay had a much lower sensitivity for extrauterine disease than either CA 125 or CA 15-3. When these two tumor-associated antigen assays were used in conjunction with CA 125 levels, there was no significant improvement in the combined sensitivity or specificity for predicting the presence or absence of extrauterine metastasis versus CA 125 values alone.

Our data suggest that preoperative determination of serum tumor-associated antigen levels is not helpful in the routine evaluation of women with endometrial carcinoma. In our experience it appears that these tumor-associated antigen assays lack the sensitivity and specificity to reliably predict subclinical metastatic disease, although elevated levels frequently occur in patients with bulky metstasis.

Maternal serum α-fetoprotein levels in pregnancies complicated by diabetes: Implications for screening programs

Alice O. Martin, PhD,[a] Lisa M. Dempsey, MS,[a] John Minogue, DMin,[a] Kiang Liu, PhD,[b] James Keller, MD,[a] Ralph Tamura, MD,[a] and Norbert Freinkel, MD[c, d, e]
Chicago, Illinois

Maternal serum α-fetoprotein may be reduced in diabetic pregnancies, but the association with elevated glycosylated hemoglobin has been controversial. We tested the hypothesis that reductions in maternal serum α-fetoprotein may reflect the same phenomena that can also impair normal rates of embryo growth in the presence of poorly compensated maternal diabetes. If so, associations would be expected among maternal serum α-fetoprotein, embryo rates of growth, and levels of glycosylated hemoglobin reflective of regulation of maternal diabetes during the period of organogenesis. We found maternal serum α-fetoprotein levels in 93 pregnant patients with diabetes to be negatively associated with the earliest (4 to 12 weeks) glycosylated hemoglobin determinations. At glycosylated hemoglobin values >9.6% (which approximates the upper quartile), all maternal serum α-fetoprotein values fell below the median for patients without diabetes (below 0.8 multiple of the median after weight adjustment). Moreover, there was a trend for pregnancies with lower maternal serum α-fetoprotein levels and higher glycosylated hemoglobin values to also demonstrate early fetal growth delay as measured by ultrasonography. (Am J Obstet Gynecol 1990;163:1209-16.)

Key words: Diabetes, maternal serum α-fetoprotein, glycosylated hemoglobin, fetal growth, neural tube defects

Ultrasonic monitoring from weeks 7 to 14 has indicated that delayed growth during early development may occur in some pregnancies complicated by diabetes.[1-3] The magnitude of the delay in growth has been correlated with the degree of antecedent and prevailing disturbance in maternal metabolism as gauged by elevations in glycosylated hemoglobin at that time.[4] The retarding effect of poorly regulated maternal diabetes on embryo growth has also been confirmed by direct analyses of conceptuses excised at the early postimplanation stage from rats rendered experimentally diabetic by the administration of streptozocin before conception.[5] These findings have suggested that aberrant fuel metabolism in the mother can compromise normal developmental timetables, and are consistent with the hypothesis of "fuel-mediated teratogenesis" proposed by Freinkel.[6, 7] The relationships may also be relevant to the recent reports of lower values for maternal serum α-fetoprotein (AFP) in diabetic pregnancies,[8, 9] and to

the conflicting literature concerning the magnitude and temporal aspects of the association between maternal serum AFP and maternal glycosylated hemoglobin.[10-12]

Correction factors linked to glycosylated hemoglobin have been proposed for the observed maternal serum AFP values in pregnancies complicated by diabetes on the assumption of some linear relationship.[11] It has also been suggested that glycosylated hemoglobin levels be checked in women with diabetes and that adjustments only be made on maternal serum AFP from women whose diabetes is not well controlled, rather than correcting maternal serum AFP values from all pregnant women with insulin-dependent diabetes with low maternal serum AFP values.[10] We believe that these corrections may belie the complexity of the true relationships between developmental events, glycosylated hemoglobin, and maternal serum AFP and note that application of such corrections has not been shown to increase sensitivity and specificity. If the sites for maternal serum AFP production are regulated by the same fuel-related phenomena that determines retardation of embryo growth, an attenuation of maternal serum AFP levels might be anticipated.[10] Moreover, the degree of attenuation should bear some relationship to the disturbance in maternal metabolism during embryogenesis (as judged by glycosylated hemoglobin in early pregnancy) and by the impact of the faulty metabolism on the manifest growth of the conceptus shortly thereafter (as judged by early ultrasonography). Because glycosylated hemoglobin reflects blood glucose levels 4 to 8 weeks before sampling, values taken after 12 weeks of pregnancy may not reveal these associations.

To test the above hypotheses, we determined whether (1) maternal serum AFP values are associated with the degree of diabetic control during embryogenesis, as measured by glycosylated hemoglobin in early in pregnancy (4 to 12 weeks) rather than closer to the time of the sampling for the estimation of maternal serum AFP (14 to 24 weeks) and (2) whether delayed fetal growth is correlated with maternal serum AFP and the early glycosylated hemoglobin values.

Material and methods

Sample. Data were collected for patients seen at Prentice Women's Hospital and Maternity Center of Northwestern Memorial Hospital. (The project had the approval of the Human Subjects Committee of Northwestern University.) Maternal serum AFP screening has been routinely offered since 1984.[13] We examined records from 1985 to 1988 of our patients with diabetes and selected all women with diabetes who also had maternal serum AFP screening. Only the latest pregnancy of each woman was included in the sample so that each could be considered independent for purposes of statistical analysis. Multiple pregnancies were excluded. We selected two of the glycosylated hemoglobin determinations available for each woman: (1) the earliest value obtained in the most recent pregnancy (67% between 4 and 12 weeks) as a measure of diabetes control before entering our program; and (2) that value obtained closest in time to when the maternal serum AFP sample was taken (96% between 14 and 24 weeks). For nine women, only one glycosylated hemoglobin value was available; this value was used as both an "early" and "closest" one. Each patient's clinical class was noted. The outcome of all pregnancies was determined. The 93 patients with diabetes (White classes B to R) ascertained in this manner were compared with 4674 nondiabetic controls screened for maternal serum AFP during the same period. Information on maternal weight at the time that maternal serum AFP was measured was available for 51 diabetic and 1129 nondiabetic pregnant women.

Estimation of gestational age for maternal serum AFP standardization and glycosylated hemoglobin selection. Information on gestational age obtained from patient records included last menstrual period and all dates determined by ultrasonography. Gestational age on the basis of consideration of all available data was calculated according to the specifications of Depp[14] and used for standardization of maternal serum AFP and for selecting the two glycosylated hemoglobin values used in our study.

Maternal serum AFP values. The laboratory values of maternal serum AFP were expressed as nanograms per milliliter for each week of gestation using the Abbott polyclonal enzyme immunoassay (Abbott Labs., North Chicago) for 71 patients. An additional 22 patients had maternal serum AFP determinations by the Kallestad AFP/OB radioimmunoassay kit (Kallestad Laboratories Inc., Austin, Tex.) during 1985.[13] Multiples of the median were computed from internal standards based on maternal serum AFP distributions computed for each gestational week for each assay. The distributions were also examined after application of weight corrections using the formula for expected multiples of the median $= 10^{[0.2658 - 0.00188\,(\mathrm{lbs})]}$.[14]

Glycosylated hemoglobin levels. Glycosylated hemoglobin determinations in the hospital laboratory are made at regular intervals during pregnancies of diabetic women at our center with gel electrophoresis (Corning, Medfield, Mass.). Mean values for nongravid, nondiabetic individuals have averaged 6.2% with a standard deviation of 0.85% (range, 5.3% to 7.2%).

Fetal growth delay. For determination of fetal growth delay, gestational age based on last menstrual period was compared with that based on ultrasonography. A Kallestad diagnostic wheel was used to convert last menstrual period to gestational days at the time of ultrasound dating. The ultrasonographic estimate

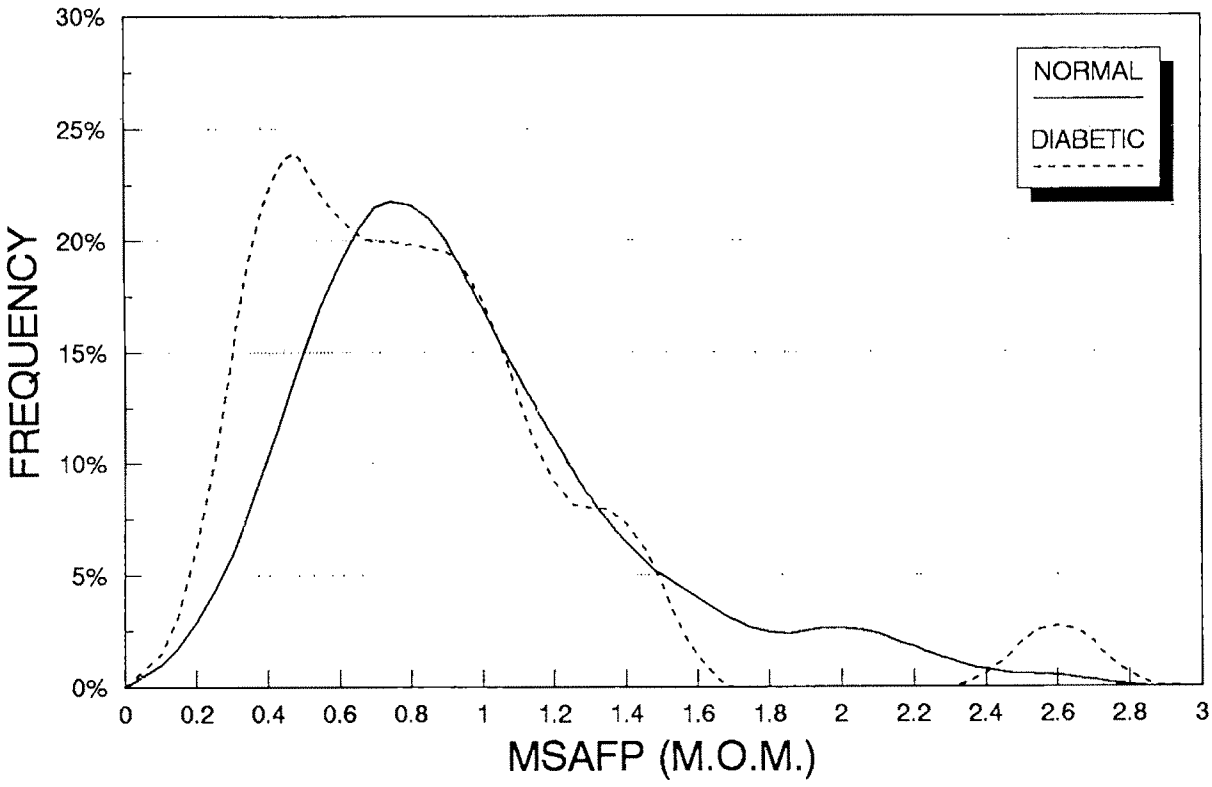

Fig. 1A. Distribution of maternal serum AFP values in diabetic women (n = 93) compared with nondiabetic women (n = 4674). Units are multiples of median.

of gestational age was obtained by the crown-rump length[15] closest to 14 weeks (range, 5 to 13 weeks). This value was the average of three measurements made with dynamic-image ultrasonography by described methods.[16] Forty-one of the 93 patients with diabetes had both last menstrual period and crown-rump length information available. These two estimates in days were then compared.

Fetal growth delay in these 41 patients was defined by two separate criteria based on whether ultrasonography provided lower estimates than last menstrual period (1) by ≥6 days, the criteria used by Pedersen et al.[2,4] for early fetal growth delay; and (2) by ≥4 days, criteria accepted by ultrasonologists in our institution as evidence of delay. Means for glycosylated hemoglobin and maternal serum AFP (multiples of the median) were compared separately in those two groups versus all others. In addition, correlation coefficients were determined between (glycosylated hemoglobin and maternal serum AFP) and all the differences in gestational age estimates, regardless of direction or magnitude.

Statistical analysis. The distribution of maternal serum AFP in women with diabetes was compared with that of women without diabetes by χ^2 analysis. A comparison was also made after adjusting maternal serum AFP for weight.

Product-moment correlation coefficients were computed between glycosylated hemoglobin and maternal serum AFP for all diabetics with either the earliest glycosylated hemoglobin assay, or the value of glycosylated hemoglobin obtained closest to when the maternal serum AFP sample was obtained. Correlations were also computed between glycosylated hemoglobin or maternal serum AFP and all differences in gestational age estimates regardless of direction or magnitude. Mean glycosylated hemoglobin (early) and maternal serum AFP levels for fetuses with growth delay were compared with all others by t tests. These comparisons were made separately using criteria for delay of ≥6 days and ≥4 days. These two comparisons are not independent.

Maternal serum AFP distribution in women with diabetes. There is a significant shift in the distribution of maternal serum AFP in diabetic women toward lower values ($\chi^2_5 = 11.07$, $p < 0.05$) (Fig. 1A). Weight adjustment improved the fit of diabetic to nondiabetic distributions ($\chi^2_5 = 7.24$, $p > 0.05$) (Fig. 1B).

Association between maternal serum AFP and glycosylated hemoglobin. By inspection, no linear association was readily apparent between maternal serum AFP and either glycosylated hemoglobin value, although the correlation coefficient is significant ($p <$ 0.05) for the earliest glycosylated hemoglobin (r =

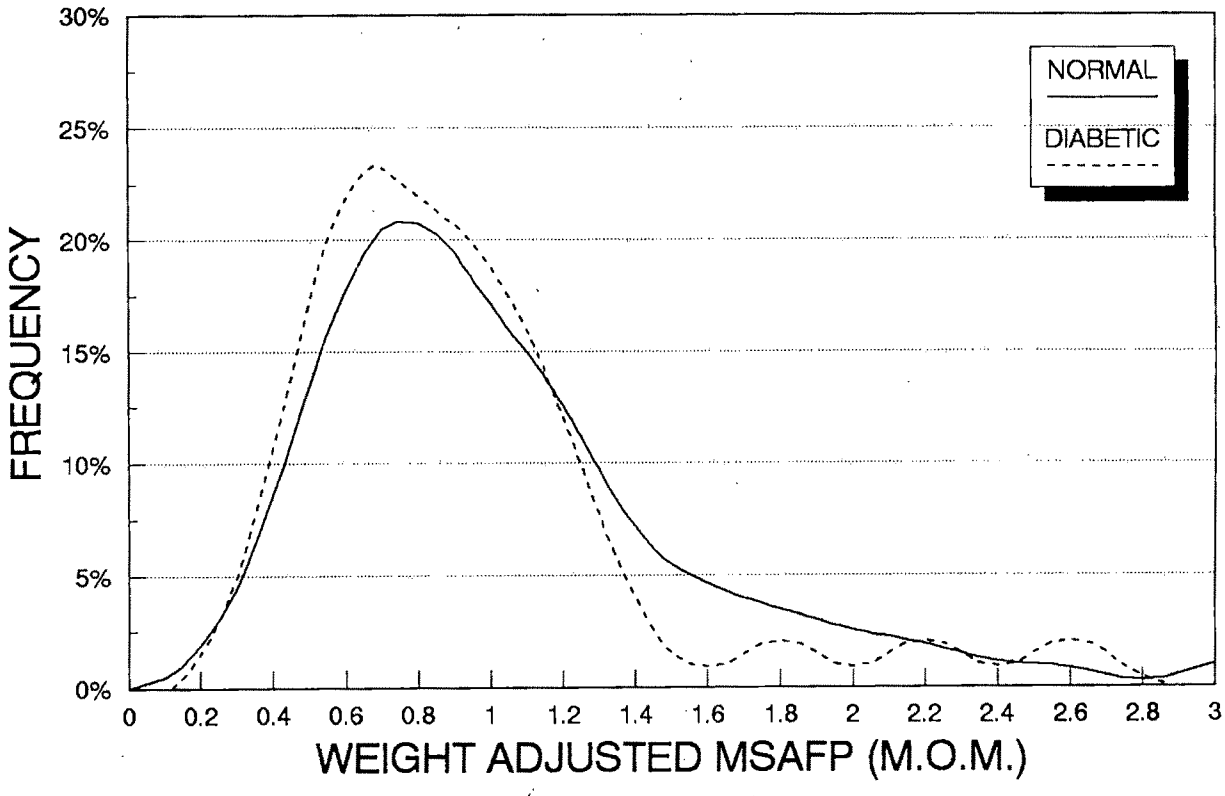

Fig. 1B. Distribution of maternal serum AFP values after adjustment of weight (diabetic, $n = 51$; nondiabetic, $n = 1120$).

-0.20, $r = -0.25$ after weight adjustment). The nature of the association becomes clearer when the highest values (upper quartile) of glycosylated hemoglobin are compared with the other three quartiles. Values for maternal serum AFP are scattered about the median for nondiabetic subjects up to a value for the *early* glycosylated hemoglobin of approximately 9.6% (Fig. 2A). (This would be approximately 4 SDs above the mean for normal, nonpregnant persons, according to glycosylated hemoglobin determinations as performed in our hospital laboratory.) Above this level, all maternal serum AFP values fell below the median for nondiabetic patients. This accounts for approximately 25% of the diabetic population with a mean maternal serum AFP in that quartile of 0.68 in contrast to mean values of 0.84, 0.82, and 0.86 in the other quartiles. This association was noted with either assays of maternal serum AFP (Kallestad or Abbott) and persisted after adjusting maternal serum AFP for weight (Fig. 2B). This relationship was not evident for glycosylated hemoglobin values obtained closer to the time of maternal serum AFP sampling (i.e., later glycosylated hemoglobin).

Fetal growth delay, maternal serum AFP. Our subset of 41 patients for whom we had also obtained early estimates of crown-rump length by ultrasonography was representative of our total patient population of 93 in exhibiting a similar association between glycosylated hemoglobin and maternal serum AFP ($r = -0.31$). Estimates of embryo size by early ultrasonography compared with gestational age that is based on last menstrual period show that last menstrual period estimated dates are generally greater than those based on ultrasonography (29/41). Nonetheless, when we used "at least 6 days" (32% of our sample)[2,4] or "at least 4 days" (i.e., 43% of our sample) as the criteria for "delayed growth," we found that this population displayed a general shift toward lower values for maternal serum AFP and higher values for glycosylated hemoglobin (Table I). Although these results are in the direction predicted by our hypothesis, the differences between mean maternal serum AFP and glycosylated hemoglobin of those with "delayed growth" versus those with "normal growth" were not statistically significant by t tests. This is probably a result of small sample sizes, and a larger series may be necessary for definitive configuration.

Although anomalies were recorded in nine of the 91 live-born infants, no neural tube defects were found. The only major malformations occurred in two infants, one with a congenital heart defect (univentricular heart with tricuspid artesia; this infant also had a hemivertebra and scoliosis, maternal serum AFP = 0.76, and

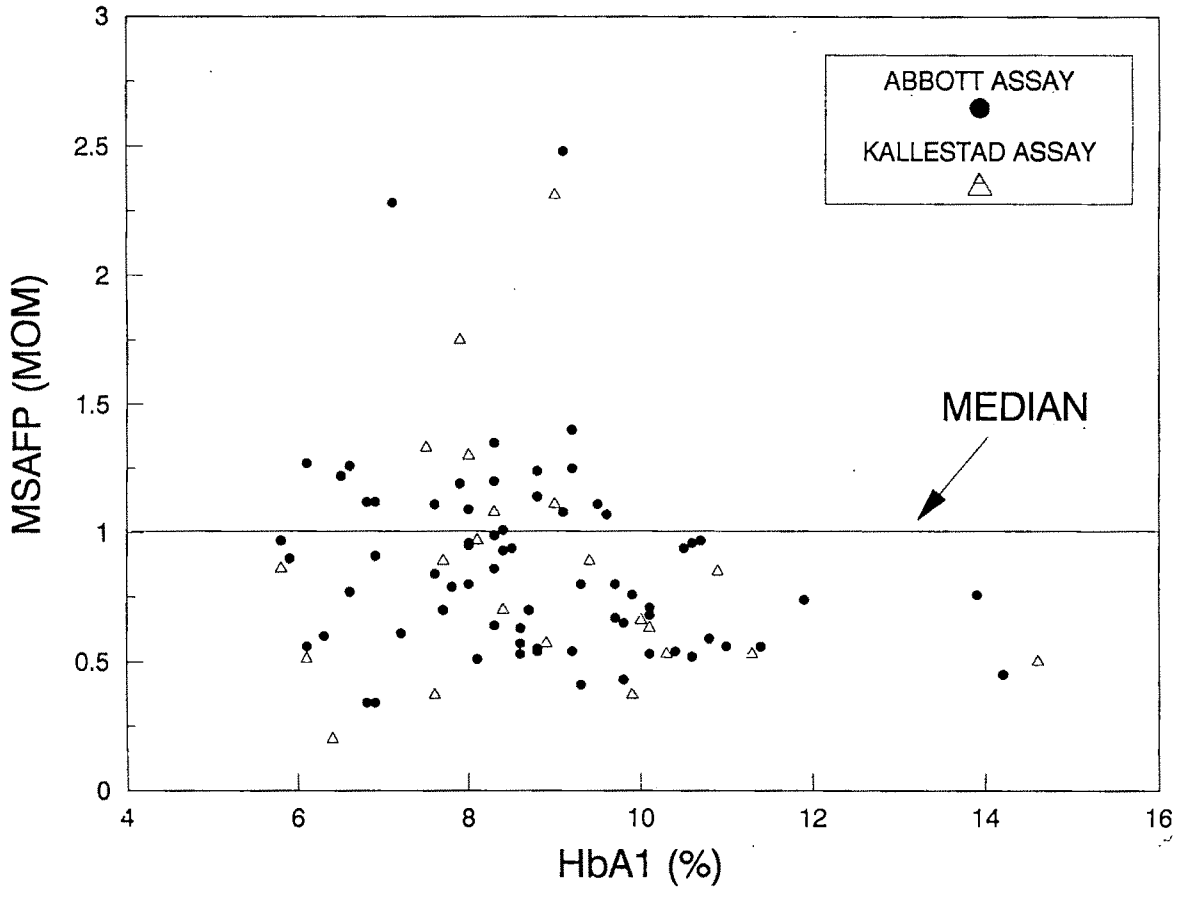

Fig. 2A. Bivariate distribution of maternal serum AFP (multiples of median) and earliest glycosylated hemoglobin levels in 93 diabetic women (three are overlapping values). Values obtained with Abbott maternal serum AFP assay are distinguished from those with Kallestad assay.

early glycosylated hemoglobin = 13.9%); and one had a cystic adenomatoid malformation of the lung (maternal serum AFP = 0.43, and early glycosylated hemoglobin = 9.8%). One infant of a 44-year-old mother had Down syndrome (maternal serum AFP = 0.53, glycosylated hemoglobin = 10.1%). Too few anomalies were found in the subset with data available on early ultrasonography glycosylated hemoglobin, and maternal serum AFP to perform formal analysis of the predictive value of these parameters, although both infants with major birth defects were associated with glycosylated hemoglobin values >4 SDs from the mean of normal values, and with maternal serum AFP below the median.

Comment

We examined the relationship between maternal serum AFP and glycosylated hemoglobin levels in 93 pregnancies complicated by diabetes and the associated ultrasonographic patterns of early fetal growth in 41 of these cases. We found that reduction in maternal serum AFP values occurs when the metabolic disturbances are most pronounced during early pregnancy, as judged by glycosylated hemoglobin values obtained when the patient first entered our program (67% during weeks 4 through 12). These values reflect the regulation of maternal diabetes during the periconceptual interval when embryogenesis takes place. At glycosylated hemoglobin values of approximately 9.6% (that is, >4 SDs over the normal mean values in our hospital laboratory) and within the upper quartile for the diabetic gravid patient in this series, all maternal serum AFP values were below the median (below 0.8 multiples of the median after adjustment for weight). Later values for glycosylated hemoglobin values obtained near the time of maternal serum AFP sampling were not as informative. The latter are less likely to reflect the regulation of maternal metabolism that prevailed during embryogenesis. At present we cannot explain the temporal discrepancies in our study and the findings of Reece et al.[10] of "inverse correlation between maternal serum AFP and the concentration of glycosylated hemoglobin when both assays were done within 6 weeks of each other (n = 47) . . . but not when glycosylated

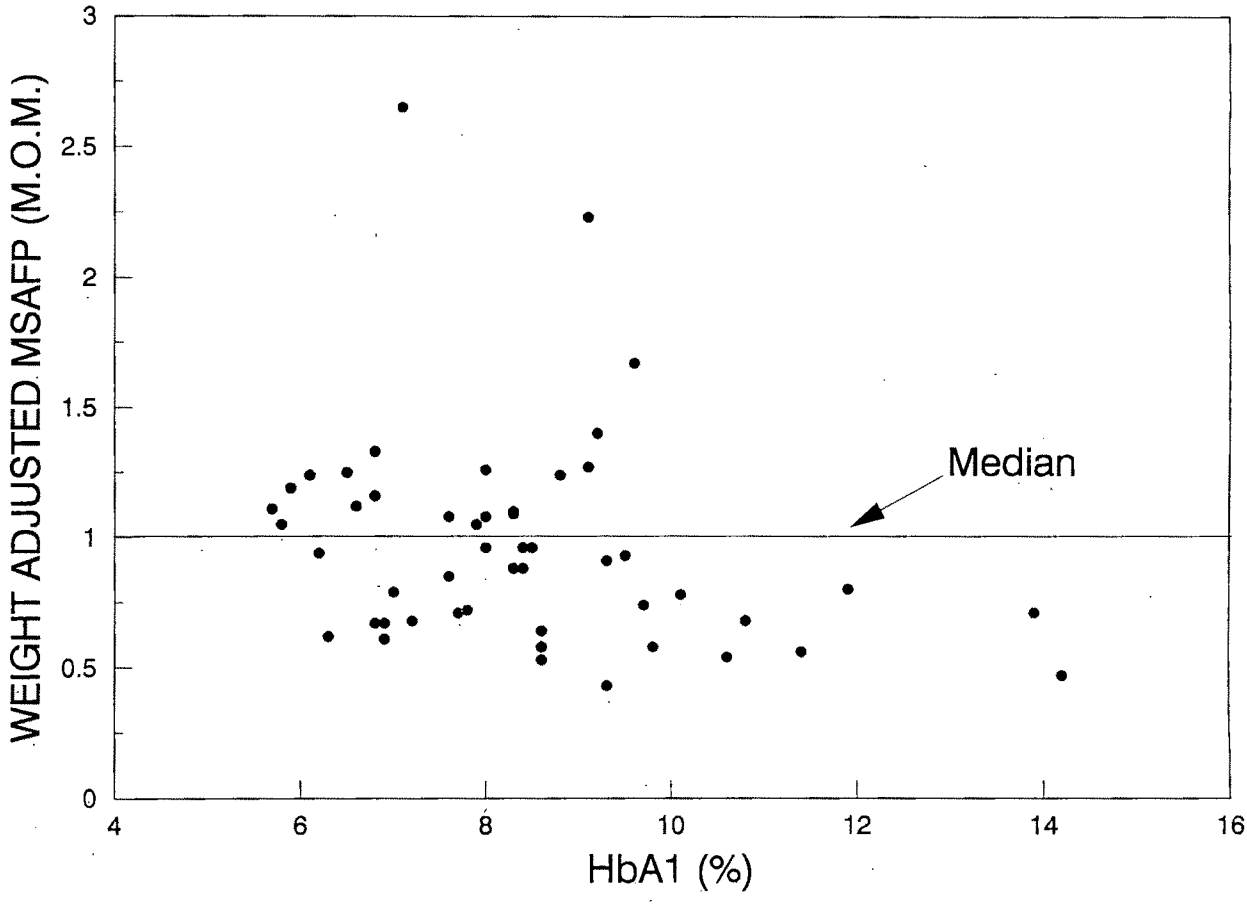

Fig. 2B. Distribution of glycosylated hemoglobin and maternal serum AFP after adjusting the latter for maternal weight. All of these assays were performed with the Abbott test kit (n = 51).

hemoglobin was measured in the first 2 months of gestation (n = 26)."

In view of these findings, discrepancies in glycosylated hemoglobin (or hemoglobin A_{1c}) and maternal serum AFP associations among several of the studies may be explained by the proportion of women with high glycosylated hemoglobin (or hemoglobin A_{1c}) in these reports, the time in gestation at which the specimens for glycosylated hemoglobin were obtained, and the laboratory values defining the upper quartile. Negative correlations are unlikely to appear if there are no increased levels of glycosylated hemoglobin, as is to have been the case likely in the nondiabetic pregnancies in which Baumgarten and Robinson[11] found no asso-

ciations. Because the association in our study does not appear to be linear, statistical tests that assume linearity are questionable, although the correlation coefficient was significant in both our series and the studies by Baumgarten and Robinson.[11] Indeed, the apparent discrepancies between the finding by Greene et al.[12] of no association and the negative associations that we and others have observed, may be reconciled by noting that the data of Greene et al. also show a decrease in maternal serum AFP in the upper quartile of glycosylated hemoglobin, >9.4% as evident in our data (means = 0.84, 0.82, 0.86, 0.69). Moreover, in the scattergram presented by Baumgarten and Robinson,[11] maternal serum AFP values are reduced in the two patients in their series whose values for glycosylated hemoglobin were >4 SDs above the mean value for their normal pregnant women.

The postulated interrelationship of maternal serum AFP and glycosylated hemoglobin has particular significance with regard to the use of maternal serum AFP as a predictive index of birth defects, fetal distress, and chromosomal aberrations. It has been shown that the incidence of birth defects is increased in fetuses with early growth delay,[2, 3] presumably when metabolic abnormalities are at their highest level.[4] If so, a biphasic consequence might result. The delayed growth would *reduce* maternal serum AFP levels, in some way linked to the factors responsible for growth retardation, and the attendant birth defects or fetal distress would *elevate* maternal serum AFP values as a consequence of lesions at the site of the birth defect. Thus a normalization of maternal serum AFP might result as a consequence of these two opposing vectors. In view of these diverging possibilities, some estimate of embryo size as judged by early ultrasonography may be useful as an additional parameter for interpreting maternal serum AFP values, especially when the likelihood of birth defects in early diabetic pregnancy is greatest.

Justification for adjustment of maternal serum AFP levels for weight, race, diabetic status, or glycosylated hemoglobin level has been based on observations that maternal serum AFP distributions vary according to those factors. However, improved sensitivity and specificity must be established as resulting from application of these proposed corrections before they are applied for clinical screening. Indeed, because the prevalence of neural tube defects varies as a function of some of these variables, (e.g., maternal diabetes[8, 9]), and because the distribution of maternal serum AFP in affected fetuses when their mothers are classified by diabetic status is unknown, applying corrections could reduce sensitivity. This untoward outcome has been suggested for nondiabetic pregnancies using weight adjustments.[17]

The only major malformations noted in our series were a congenital heart defect and a hemivertebra and scoliosis in one infant, and a tumor of the lung in another. No neural tube defects were noted. Although maternal serum AFP values were low in both those infants and glycosylated hemoglobin levels were elevated well in excess of 4 SDs from the normal mean in our hospital laboratory, the numbers were too small for formal analysis of the interrelationship.

We observed a trend of both low maternal serum AFP and high glycosylated hemoglobin values in pregnancies that exhibited fetal growth delay, supporting our hypothesis that altered maternal metabolism effects on fetal growth are reflected in lowered maternal serum AFP. Larger sample sizes including more fetuses with anomalies and delayed growth will be needed to elucidate the overall associations. In the interim we suggest rather than applying corrections to maternal serum AFP, other than perhaps for weight, that special attention be paid to pregnancies with low unadjusted maternal serum AFP, or with elevated glycosylated hemoglobin values, or both, in the first trimester. If the glycosylated hemoglobin data are unavailable for that period, the maternal serum AFP level after 15 weeks may be a valuable indicator of earlier lack of control during embryogenesis and organogenesis, based on the negative association we report. Determination of glycosylated hemoglobin in the second trimester may not be a useful adjuvant because glycosylated hemoglobin reflects control 4 to 8 weeks earlier, which in this case may not be indicative of developmental problems that would have occurred earlier. Early determination of crown-rump length by ultrasonography may be recommended as an additional parameter for interpretation of maternal serum AFP. If further experience supports our preliminary findings, the triad of maternal serum AFP, glycosylated hemoglobin, and early ultrasound, considered jointly, may well provide the most accurate determination of teratogenic risk in pregnancies of diabetic women complicated by diabetes mellitus.

We thank Robert Mardur, MD, Jayme Borensztajn, MD, and the Department of Pathology for performing the laboratory assays, and Patricia Lathion, who assisted in the preparation of this article.

High infectious morbidity in pregnant women with insulin-dependent diabetes: An understated complication

Eric F. Stamler, MD,[a] Maria L. Cruz, MD,[b] Francis Mimouni, MD,[b] Barak Rosenn, MD,[a] Tariq Siddiqi, MD,[a] Jane Khoury, MS,[c] and Menachem Miodovnik, MD[a]

Cincinnati, Ohio

Patients with insulin-dependent diabetes are prone to infection, possibly related to poor metabolic control. Relative immune deficiency exists in pregnancy. We hypothesized that pregnant patients with insulin-dependent diabetes are at an increased risk for infection and that infection is related to poor glycemic control. We matched 65 pregnant women with insulin-dependent diabetes to 65 nondiabetic pregnant controls. At least one episode of infection before delivery occurred in 83% of the women with insulin-dependent diabetes (26% in control group). The rate of postpartum infection was five times higher in the group with insulin-dependent diabetes and they were susceptible to more kinds of infections. Although there was no overall difference among the indices of glycemic control, hemoglobin A_1 obtained before the infection was higher than during infection. We conclude that a high rate of infection exists in pregnant women with diabetes; infection and poor glycemic control may be associated, but it is unclear whether improvement in metabolic control will reduce this high infection rate. (Am J Obstet Gynecol 1990;163:1217-21.)

Key words: Diabetes, pregnancy, infection, glycohemoglobin

Patients with insulin-dependent diabetes are at high risk for infection.[1] Several deficiencies in the immune mechanism involving defective leukocyte and lymphocyte activity[2-6] may explain their propensity to infection. These deficiencies appear to be linked to poor glycemic control.[4-6]

Pregnancy is also generally thought to constitute a state of relative immune deficiency, specifically, impaired cell-mediated immunity.[7-10] Thus pregnancy in the patient with insulin-dependent diabetes is likely to represent an additional risk factor for infection.

This study was designed to test the hypotheses that (1) pregnant patients with insulin-dependent diabetes have a higher rate of antepartum and postpartum infections when compared with a pair-matched control population, and (2) high infection rates in pregnancy patients with insulin-dependent diabetes correlate with poor glycemic control. Specifically, glycemic control during pregnancy is related to infection in pregnancy and glycemic control in the third trimester is related to postpartum infection.

Material and methods

In an interdisciplinary program at the University of Cincinnati designed to study the effects of glycemic control on the course and outcome of pregnancy in patients with insulin-dependent diabetes, 307 pregnancies in diabetic patients were prospectively followed from 1978 to 1988. To avoid possible biases and the confounding effect of preterm or prolonged rupture of membranes, labor, or vaginal deliveries on the incidence of infection, only 65 patients with insulin-dependent diabetes delivered by elective cesarean section for previous cesarean delivery were included in this study. According to White's classification, 16% of these patients with insulin-dependent diabetes were in class B, 33% were in class C, and 51% in class D to RT. The study group was retrospectively compared with a control group of 65 nondiabetic controls (normal glucose challenge at 28 weeks' gestation[11]) who were also delivered by repeat elective cesarean section. Control patients were randomly selected by computer after careful matching by gestation (± 2 weeks), parity, age (± 3 years), year of delivery, presence or absence of labor, and care by the same obstetrician (Table I). Complete medical and obstetric histories were recorded for each patient. Control patients were seen monthly until the thirty-sixth week of gestation, then weekly there-

after. Because the nature of their disease, patients with insulin-dependent diabetes were seen every 1 to 2 weeks.

In patients with insulin-dependent diabetes, glycemic control was obtained with split-dosage regimens of insulin using both short- and intermediate-acting preparations in combination with dietary regulation. The goals of glycemic control were a fasting blood glucose concentation of <100 mg/dl and a 90-minute postprandial glucose concentration of <140 mg/dl. Patients were hospitalized when necessary to maintain these goals of glycemic control. Maternal blood hemoglobin A_1 concentrations were measured at entry and every 4 weeks using the Isolab column chromatography, with an interassay coefficient of variation of 7.2% and a normal nonpregnant range of 5.5% to 8.5%.[12] Preprandial or postprandial capillary glucose concentration were alternately measured at each weekly visit with a reflectance meter (Dextrometer, Ames Division, Miles Laboratories, Elkhard, Ind.). Results for fasting glucose (or postprandial glucose) were averaged for each trimester and expressed as mean fasting glucose (or postprandial glucose) per trimester.

Patients were evaluated for infection only if they were symptomatic. Infections were classified according to time of onset during pregnancy (antepartum vs postpartum), by system involved (urinary, genital, gastrointestinal, respiratory, specific viral syndromes, wound infection, and endometritis), and by specific infective agent (bacterial, protozoal, viral, fungal). The following criteria were required for the diagnosis of an acute infection: (1) culture of a specific organism from a relevant specimen or positive wet smear, potassium hydroxide preparation or Gram stain from a relevant specimen for the diagnosis of vaginitis, urinary tract infection or cystitis, or wound infection; (2) physical symptoms of either fever, rhinorrhea, cough, myalgia, or headache for the diagnosis of respiratory tract infections or presumed viral syndrome; (3) physical symptoms of diarrhea, vomiting, or both for the diagnosis of gastroenteritis; (4) presence of uterine tenderness and fever for the diagnosis of endometritis.

Data were analyzed with the SAS program (SAS Institute, Cary, N.C.). Continuous data were tested for normality and were analyzed, after appropriate transformation when necessary, by means of analysis of variance techniques and Student's t test. When transformation was not possible, nonparametric techniques were used; χ^2 or Fisher's exact test were used as tests for categoric variables. Logistic regression analysis was used to determine the combined effects of factors found to be significant in univariate analysis and to test their possible interaction. Data are expressed as mean ± SEM. A p value <0.05 was considered significant.

Results

Infection rates are presented in Table II. There were significantly more women in the group with insulin-dependent diabetes who had at least one episode of infection during pregnancy than women in the control group (83% vs 26%, $p < 0.01$). Postpartum infection rates were also significantly higher in the diabetic group (24% vs 5%, $p < 0.01$). The mean number of infectious episodes per women was also higher in the group with insulin-dependent diabetes in both the antepartum (1.58 ± 0.14 vs 0.34 ± 0.08), and postpartum (0.29 ± 0.07 vs 0.05 ± 0.03, $p < 0.01$ using Wilcoxon rank-sum).

The types of infection are presented in Tables III and IV. Women in the group with insulin-dependent diabetes demonstrated significantly higher rates of urogenital, respiratory tract, wound, and endometrial infections compared with the control group. Of the various infective agents tested, only Candida infection was found more frequently in the group with insulin-dependent diabetes ($p < 0.01$).

The relationship between infection in women with insulin-dependent diabetes and glycemic control is presented in Tables V and VI. There was no significant difference in the mean hemoglobin A_1, fasting glucose, and postprandial glucose measurements in each period between the group with infection in that trimester and

the group without infection in the same trimester in both the antepartum and postpartum periods.

To further define the temporal relationship between glycemic control and infection and to remove the possible confounding effect of repeated infection on hemoglobin A_1 concentrations, we analyzed hemoglobin A_1 concentrations in two ways. (1) The mean hemoglobin A_1 obtained before the first infectious episode in women with insulin-dependent diabetes in whom infection developed was compared with the mean hemoglobin A_1 of the same women obtained around the time of the infection (within 2 weeks before to 6 weeks after the infection), and was found to be significantly higher (9.5 ± 0.31 vs 8.5 ± 0.32, $n = 34$, $p < 0.01$). (2) The mean hemoglobin A_1 at 9 weeks was compared among three groups of women: (a) those who had no infection at 9 weeks but in whom infection subsequently developed between 10 to 20 weeks ($n = 18$); (b) those who had their first episode of infection later than 20 weeks' gestation ($n = 12$), and (c) those in whom antepartum infection never developed ($n = 9$). The mean ± SEM values were 9.72 ± 0.48, 9.42 ± 0.56, and 9.06 ± 0.50, respectively (no significant differences).

Comment

Our data show that patients with insulin-dependent diabetes are at high risk for infectious complications both during pregnancy and in the postpartum period. We cannot exclude the possibility that there could have been underreporting of infections in the control group, since women in this group were not seen at follow-up as frequently as women with insulin-dependent diabetes, which could conceivably result in a spuriously inflated difference between the two groups. However, the method of reporting was similar in both groups, and only faulty recollection may have biased the results. We believe that underreporting cannot fully account for the large difference in the rates of infection between the two groups. Furthermore, the significantly higher incidence of infection in the group with insulin-dependent diabetes in the postpartum period, a time when both groups are equally followed up, strengthens the conclusion that the pregnant woman with diabetes is indeed more prone to infection.

The risks for infection in this population may be related to the relative immune deficiencies induced by diabetes. Defective leukocyte chemotaxis,[2] depressed lymphocyte response to phytohemagglutinin,[3] impaired granulocyte adherence,[4] and impaired granulocyte phagocytosis[5, 6] have been implicated. Pregnancy itself is also thought to alter host susceptibility to infection. Although humoral immunity appears to be unaltered,[9] depression of selective aspects of cell-mediated immunity, such as depressed lymphocyte proliferation and alterations in monocyte/lymphocyte ratios have been reported.[7, 8, 10] Epidemiologic evaluation of infection in pregnancy is suggestive of a change in cell-mediated immunity.[13]

The diabetic gravid woman thus poses a special therapeutic challenge to the clinician. There are few studies

of infection in diabetic pregnancies. In 1973 Vejlsgaards reported an increased incidence of urinary tract infection in diabetic gravid women compared with nondiabetic gravid women.[14] In a study restricted to postpartum infections, Diamond et al.[15] also observed an increased rate of postpartum wound infection, endometritis, or both in diabetic pregnant women. Our study confirmed these findings and evaluated a broader range of infectious agents and involved more organ systems. Our data show that diabetic gravid women are also more susceptible to gastrointestinal, respiratory, and wound infections when compared with a matched control population.

The association between glycemic control and infection is difficult to explore because infection may theoretically cause, or be caused by, poor glycemic control. Rayfield et al.[16] demonstrated a striking direct correlation between the overall prevalence of infection and the mean plasma glucose concentrations (representing three or more fasting glucose concentrations taken at times when no evidence of infection existed) in 241 nonpregnant diabetic women. Glycemic control was not evaluated in the studies by Vejlsgaards[14] and Diamond et al.[15] We attempted to relate glycemic control temporally to the incidence of infection of the women with insulin-dependent diabetes and found conflicting results. The differences in indices of glycemic control between the subgroup in whom infection developed and the subgroup in whom infection did not develop were not statistically significant. Further analysis showed that the mean hemoglobin A_1 obtained before the first infectious episode was significantly higher than

the mean hemoglobin A_1 of the same women obtained around the time of infection. Although the clinical significance of a small difference in hemoglobin A_1 concentrations may be doubtful, the theoretic implications of such a difference may be valuable. Because glycemic control is ordinarily hampered during infection and hemoglobin A_1 level was actually higher *before* the infection than *during* the infection, this may favor the thesis that poor glycemic control temporally precedes infection. Since hemoglobin A_1 gradually decreases as pregnancy progresses and glycemic control is achieved,[17] it is difficult to ascertain whether the statistically significant difference in hemoglobin A_1 before and during the infection can be attributed to this natural decline or to the relationship between glycemic control and infection. Thus the specific role of glycemic control in the aggravation of the risk of infection in pregnancy remains unanswered.

In conclusion, despite advances in current medical care, the diabetic pregnant woman is at significant risk for the development of infection involving most organ systems in both the antepartum and postpartum periods. Infection appears to be associated with poor glycemic control, but the temporal relationship is difficult to analyze. Whether further improvement in metabolic control will reduce the risk for infection in the pregnant woman with insulin-dependent diabetes is unclear at this time.

The effect of race on the relationship between fetal death and altered fetal growth

Richard Ferguson, MS,[a] and Stephen A. Myers, DO[b]
Chicago, Illinois

This population study examines racial differences in the relationship between birth weight and fetal death. An earlier report showed that a birth weight that results in a fourfold increased risk of stillbirth is not a constant birth weight percentile (2nd percentile at 25 weeks, 17th percentile at 42 weeks). This analysis was applied to 782,430 white and black births in Illinois from 1980 to 1984. Mean and 10th percentile growth for white and black infants is identical before 34 weeks' gestation and growth diverges by 250 gm at term, with white infants being larger. Race-specific birth weights resulting in quadrupling of the stillbirth rate were determined with an exponential regression analysis of the relationship between birth weight and fetal death rate for each gestational age. The data indicate (1) that the birth weights resulting in quadrupling the stillbirth rate are substantially above the Denver 10th percentile and the previously unpublished race-specific Illinois 10th percentiles and (2) that at term white infants demonstrate this constant risk at the 12th percentile, whereas black infants exhibit the risk at the 18th percentile. From these data we conclude that black fetuses are more sensitive than white fetuses to factors that adversely affect growth and that continued use of "race-neutral" data for clinical management in racially heterogenous populations will not accurately predict the risk of stillbirth. (AM J OBSTET GYNECOL 1990;163:1222-30.)

Key words: Race, growth, birth weight, fetal death

The clinical evaluation of altered fetal growth during pregnancy largely depends on identification of fetuses predicted to lie below some standard point for any given gestational age, usually below the 10th percentile for birth weight. After birth the diagnosis is either confirmed or refuted with a similar approach. In a previous analysis of >850,000 births in Illinois between 1980 and 1984, we found that the 10th percentile of birth weight does not result in a constant outcome at each gestational age.[1] Specifically, quadrupling of the fetal death rate occurs at the 2nd percentile of birth weight at 25 weeks compared with the 17th percentile at 40 weeks' gestation. Moreover, the birth weights at which this increased fetal death rate occurs differ considerably from the published Denver 10th percentile and, importantly, from the previously unpublished Illinois 10th percentile curve.[1]

The effect of race on the relationship between birth weight and gestational age has received some attention over the years in the medical literature.[2-8] However, it is still common practice to evaluate altered growth by using "race-neutral" criteria.[9] The purpose of this study is to examine the effect of race on the outcome-oriented risk assessment previously reported, as determined by the birth weight that results in the quadrupling of the stillbirth rate versus gestational age. If substantial differences in race-specific outcome data exist, the further utility of "race-neutral" data for clinical management would be questioned.

Material and methods

The state of Illinois computer data file of all births in Illinois between 1980 and 1984 contains data on 796,475 singleton births for which either birth or death certificate includes birth weight, gestational age, and white or black race. Working certificates are completed at the hospital of birth and are sent to the Illinois Department of Public Health where final certificates are prepared and the data entered into the computer data file. In Illinois 10% of the live births are to Hispanic mothers. However, until 1988 no separate identifier was present on the Illinois fetal death certificates. Therefore, separate Hispanic analysis could not be performed.[10] For white and black infants, we determined the number of fetal deaths at each gestational age along with race-specific mean and modal birth weights for

each gestational age using the univariate procedure of Statistical Analysis System (SAS Institute, Inc., Cary, N.C.). Obvious outliers (several newborns with birth weights >4000 gm at 25 weeks were found) were eliminated below 34 weeks by the following correction procedure. Because these outliers would affect only the mean, an assumption was made that the birth weight distribution at any given gestation was symmetric about the mode. We determined the number of 100 mg units for birth weights lower than the mode that contained at least 2% of the births for that gestational age. That number of 100 gm units was then counted off for birth weights higher than the mode. All births above that point were discarded. No correction of the data was performed beyond 34 weeks' gestational age. As a result a total of 8,637 live births and 63 stillbirths were deleted, leaving 787,775 deliveries for subsequent analysis. These corrected data were used to determine the race-specific mean birth weight and race-specific 10th percentile determinations for each gestational age (Table I).

For each race and within each gestational age group, the fetal death rate was determined for each birth weight increment of 100 gm. This was calculated by taking the number of fetal deaths divided by the total number of live births plus fetal deaths in births occurring in each 100 gm increment. Within each gestational age group, an exponential regression analysis of the relationship between birth weight and fetal death rate was made. For each gestational age, a nonlinear, inverse relationship was observed; as birth weight decreases, the fetal death rate increases in an exponential fashion. The fetal death rate at the modal birth weight was multiplied four times, and an estimate of the birth weight at which the modal fetal death rate quadrupled was determined (designated BW_{FDR4x}). This process has been reported previously in detail.[1] This procedure was repeated for each gestational age week within each racial group, and the results are tabulated both in grams and as race-specific birth weight percentile. Smoothed "curves" for mean, 10th percentile, and birth weight at which the modal fetal death rate quadrupled were constructed with use of third-degree polynomial regression analysis.

Results

The number of live births, fetal deaths, mean, and modal birth weights for each gestational age are tabulated for white and black births in Tables I and II, respectively. Table III contains the race-specific 10th percentile, and the birth weight resulting in quadrupling of the modal fetal death rate, expressed in grams and percentile for each race.

Comparison of white and black birth weight versus gestational age curves is represented in Fig. 1. As seen in the figure, the mean and 10th percentile curves are nearly identical before 34 weeks' gestation. After 34 weeks there is a gradual increase in mean and 10th percentile birth weights among whites of 250 gm by 40 weeks' gestational age.

The comparison of the race-specific 10th percentile of birth weight to the race-specific birth weight resulting in the quadrupling of the modal stillbirth rate are shown for white and black births in Figs. 2 and 3, respectively. As shown in Fig. 2, for white patients the birth weight resulting in a constant stillbirth rate is parallel to the 10th percentile, generally around the 12th percentile. In contrast, black infants do not achieve this

magnitude of risk until reaching birth weight less than the 5th percentile in earlier gestation, whereas this risk is reached with infants in the 15th to 18th percentile at term (Fig. 3).

Comment

These population-based data support two important conclusions. First, race-specific mean and 10th percentile birth weight curves for white and black newborns do not differ substantially before 34 weeks' gestation and diverge by approximately 250 gm at term. Second, the race-specific birth weight that results in quadrupling of the fetal death rate, expressed in either grams or as race-specific birth weight percentile, is not the same for white and black patients. Because both race-specific risk curves are above the race-specific 10th percentiles, and substantially above the Denver 10th percentile, continued widespread use of the Denver data must be questioned (Fig. 4, shaded areas). Fetuses or newborn within the shaded area are not currently considered either as having growth retardation or as being at substantial risk. However, as these data indicate, fetuses within this area have greater than a fourfold increased risk of stillbirth compared with their more nor-

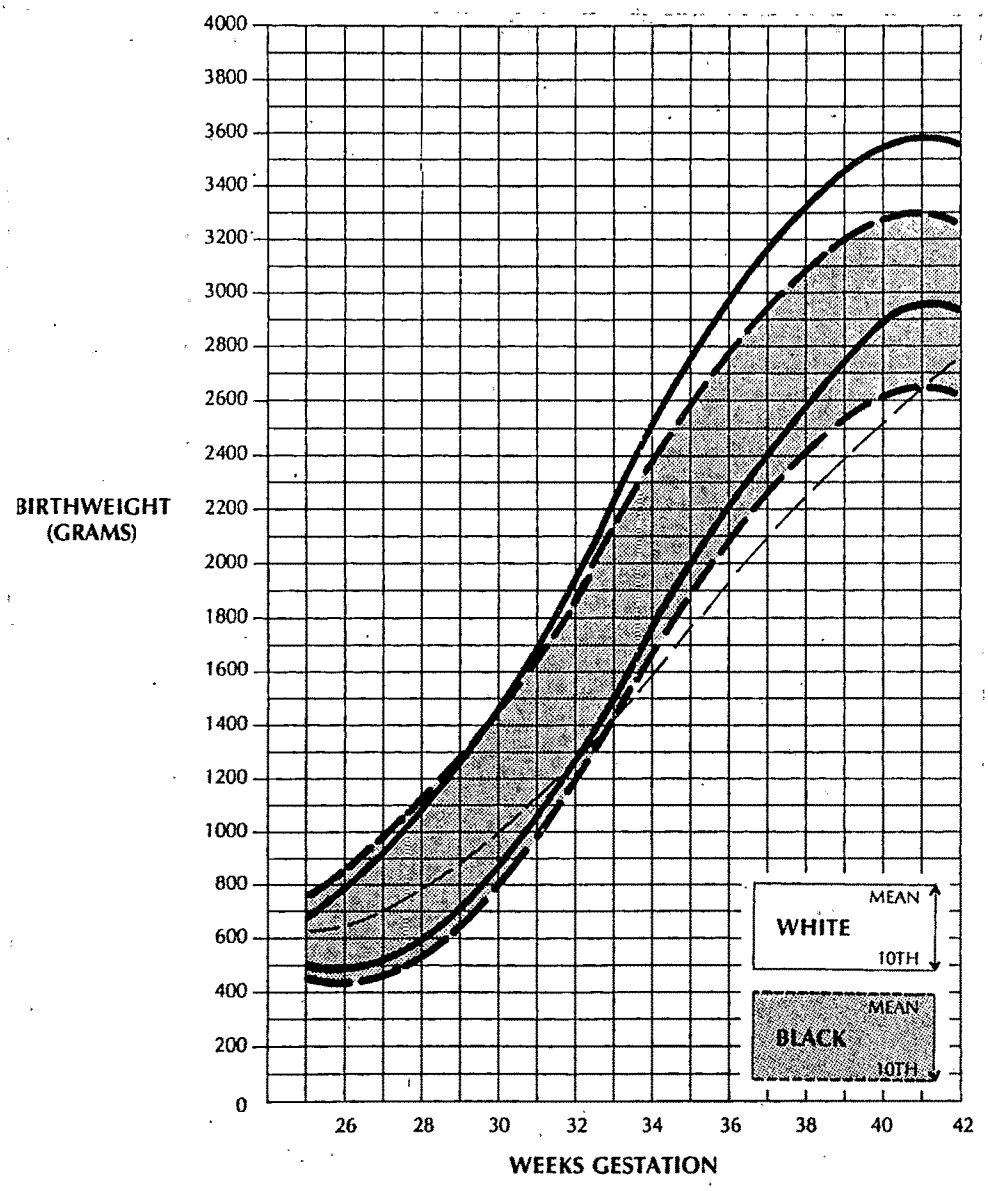

Fig. 1. Smoothed growth "curves" of mean and 10th percentile for white and black patients. *Thin lower line* represents the Denver 10th percentile.

mally grown (modal birth weight) peers. As a result significant underestimations of risk occurs for this group. This is precisely the period in gestation when the majority of nongenetic factors associated with altered growth exert their effect. Before this period the Denver data tend to overestimate risk, especially for black infants. However, since clinical recognition of intrauterine growth retardation at this stage is uncommon, this overestimation has not had much relevance. Moreover, the small sample size of Denver data at this "end of the curve" raises the possibility of statistical inaccuracy related to curve fitting accounting for much of the discrepancy, compared with the larger numbers reported from Illinois.

Relative risks calculated with both the Denver data and the race-specific data are listed in Table IV. Comparison of these risk multiples demonstrates the magnitude of underestimation that would result from continued use of those data. As seen in Table IV, for white births the use of the 10th percentile would predict an average 4.9-fold risk of stillbirth at the modal birth weight beyond 33 weeks' gestation. By comparison, use of the 10th percentile for black births would result in an average of 6.1-fold risk of stillbirth rate for the same period of pregnancy. Importantly, use of the Denver 10th percentile results in an unacceptably high relative risk of still birth: from 11 to 22 times the modal fetal death rate for white births (from 34 to 40 weeks' gestation, see table). Similarly, a somewhat smaller but comparably increased risk would result from use of the Denver 10th percentile to predict risk of stillbirth for blacks.

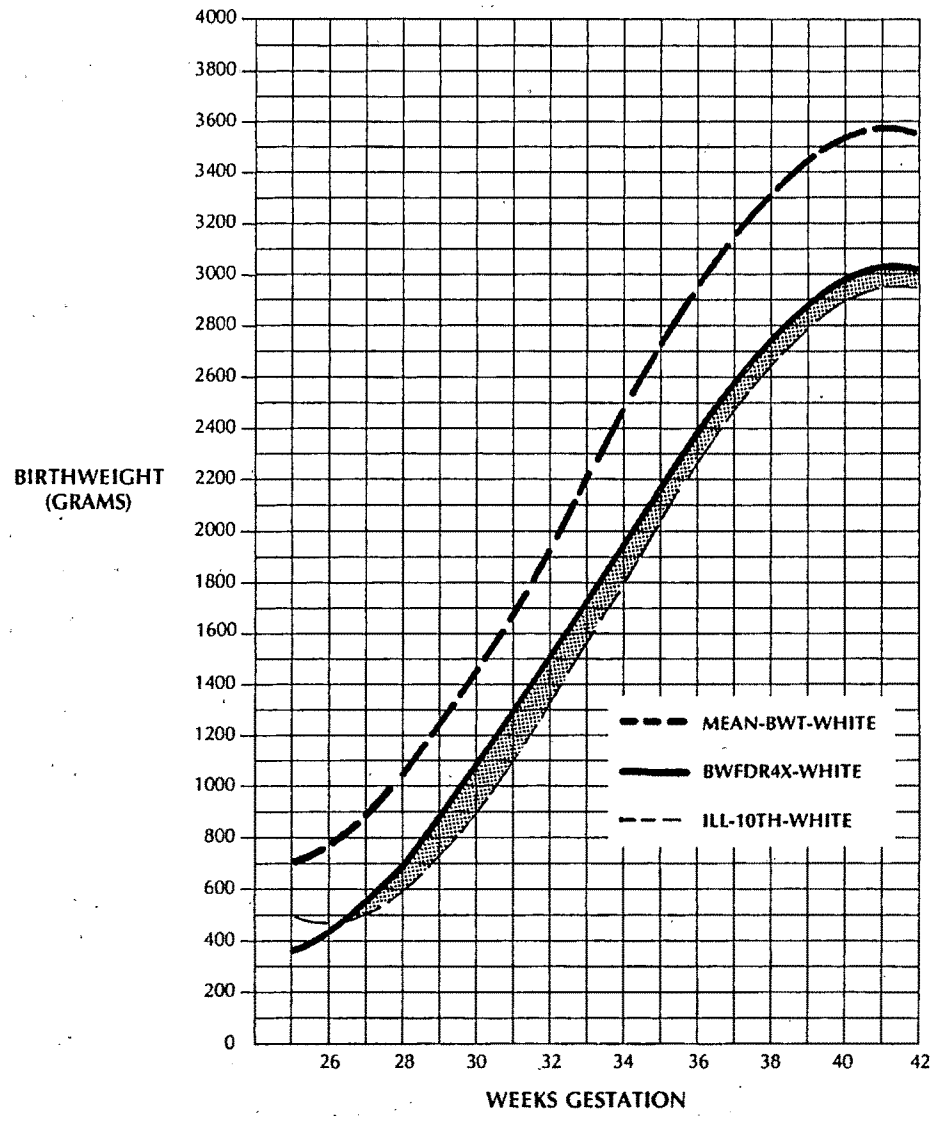

Fig. 2. Relationship between birth weight predicted to result in quadrupling of fetal death rate of each gestational age compared with 10th percentile for white patients. *Shaded area* represents birth weights underestimated to be at risk if race-specific 10th percentile were used.

There have been previous attempts to compare birth weights of white and black newborns.[2, 3, 5-9] Although some of these studies suffer from either small total samples or large data sets only after 28 to 30 weeks, the results vary little from these data. The study of Brenner et al.[8] has been consistently used as a "standard" in the United States. Although percentiles for only the pooled data (race-neutral) are recorded, race-specific mean birth weights for each race are given, but only in a figure inset and only beyond 36 weeks. In Fig. 3 of their study, a 225 gm mean birth weight difference between white and black infants is shown at 40 weeks' gestation. This does not differ much from the 250 gm difference we report at 40 weeks' gestation (Tables I and II). Unfortunately, there is no race-specific 10th percentile data in the Brenner paper. We speculate that if this had been calculated, percentiles similar to our own data would have been generated. Consequently, there is little reason to suspect that significant geographic differences exist for white and black patients. Any race-specific growth curve would be as useful in New York or California as in Chicago. Unlike the Brenner data, our population-based data includes race-specific mean and 10th percentile of birth weight for each gestational age between 25 and 42 weeks.

The relationship between percentile growth and risk has not been precisely defined in the medical literature. Problems with standards for diagnosis of growth re-

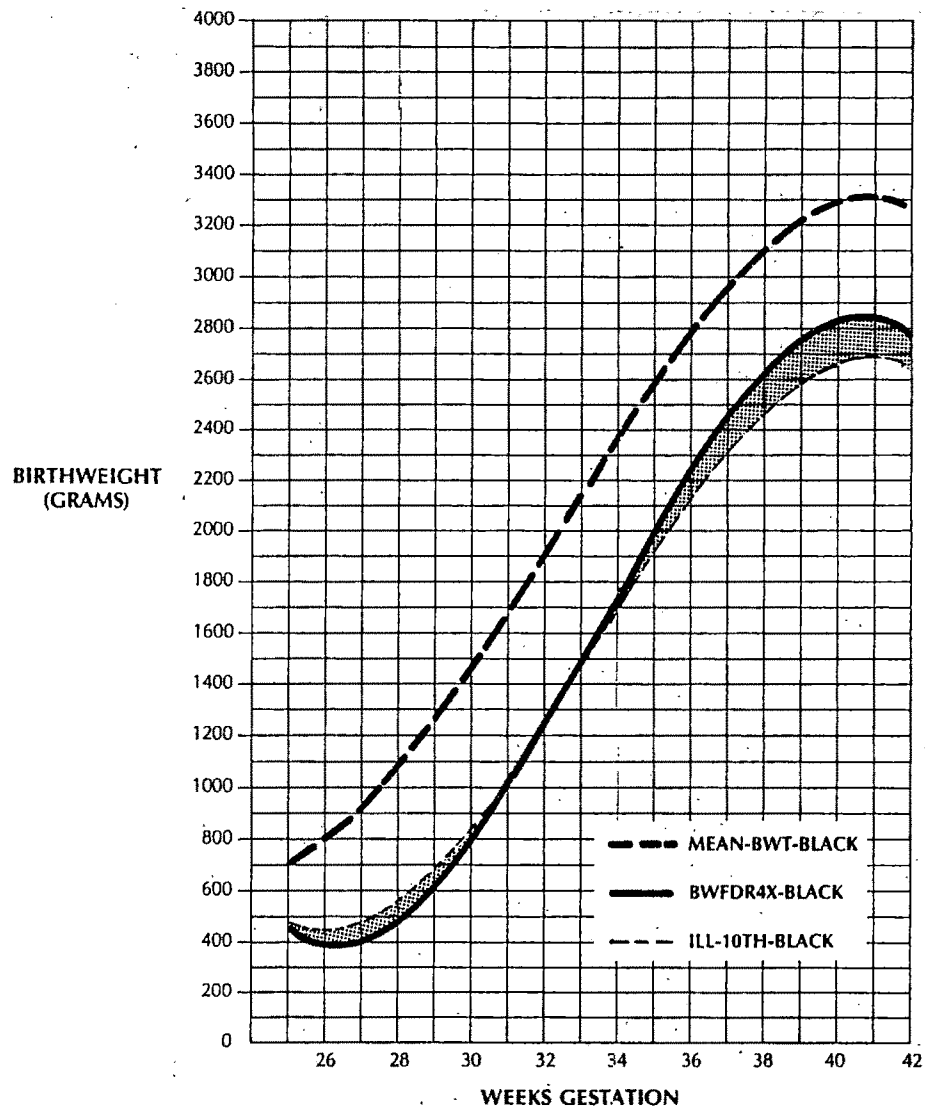

Fig. 3. Relationship between birth weight predicted to result in quadrupling of fetal death rate of each gestational age compared with 10th percentile for black patients. *Shaded area* represents birth weights underestimated to be at risk if race-specific 10th percentile were used.

tardation have recently been described by Goldenberg et al.[11] They recommended use of a national standard based on growth, at least partially recognizing difficulties related to heterogenous populations. However, they did not evaluate the use of an outcome-oriented risk assessment on determining the "standard," as discussed in our earlier analysis of this relationship. We observed that at each gestational age, the risk of stillbirth increases exponentially as birth weight decreases.[1] Unless the exponential nature of the relationship is appreciated, a tendency to underestimate risk occurs as birth weight becomes progressively smaller. Moreover, by determining an outcome-oriented criteria for assessing risk (the birth weight that results in quadrupling the stillbirth rate), we observed that this risk is not the same birth weight percentile from 25 to 42 weeks' gestation.[1] When this was observed in our earlier work, the analysis was applied with use of race-specific data to determine what racial difference in response to factors causing altered growth may exist.

When the data from the original analysis are compared with these data, it can be shown that given a population containing 20% blacks (as in Illinois), the addition of risk curves for whites and blacks would result in the curve originally reported.[1] It also follows, that as the racial make-up of any given population varies, so too would any single risk curve, and thus the 10th percentile. The continued reliance on race-

neutral, "homogenous" data sets for clinical assessments about growth, and therefore risk should be replaced. Data that is race-specific will surely result in more accurate determinations. As seen in Fig. 2, the risk curve for white patients consistently runs parallel and just above the 10th percentile, approximately the 12th percentile. In contrast, black infants demonstrate the same risk at progressively higher race-specific birth weight percentiles after 34 weeks' gestation, reaching the 18th percentile at 40 weeks. By comparison of the two race-specific birth weight percentiles resulting in the same adverse outcome, inferences about racial differences to the response to factors causing dimished fetal growth can be made. Specifically, whereas a white infant must "reach" the 12th percentile at term to have a quadrupled risk of stillbirth, a black infant has the same risk at a *larger* comparative birth weight for its race, the 18th percentile. If the exponential nature of the relationship between birth weight and fetal death is considered, it can be seen that if the black infant were to reach the 12th percentile, a five to six times increased risk of stillbirth would occur. After 34 weeks' gestation, black fetuses are more sensitive than white fetuses to factors causing altered fetal growth. The increased sensitivity results in an increased risk of stillbirth. Unless this increased sensitivity of blacks compared with whites is appreciated, further underestimations of risk for this group can occur. Similarly, although white fetuses may be relatively more resistant to altered growth, a difference of as much as 400 gm separates the white risk

Table IV. Relative risk of fetal death for white and black births

Weeks' gestation	White births		Black births

FDR, Fetal death rate.

curve from the Denver tenth percentile. As a result significant underestimation of risk for white fetuses results as long as use of the Denver 10th percentile is continued.

From a teleologic perspective, there is much to be said for the notion that, given a single gestational age group with thousands of birth weights, there is something very "normal" about the most common (modal) weight. It would appear that, given the variations in population, the modal weight is likely the birth weight "intended" for that gestational age. If the modal birth weight could be considered the most normal, we reasoned that the stillbirth rate at that weight therefore could be considered the "background" stillbirth rate for any given gestational age. The use of a factor of four was arbitrary. However, whereas doubling the stillbirth rate from 1.4 per 1000 to 2.8 per 1000 (using the 40-week gestational age group, for example)[1] could arguably be viewed as not necessarily a real increase, we reasoned that by the time a stillbirth rate quadruples, it clearly represents a negative biologic effect. Although smaller multiples may legitimately be considered as representing significant risk, the effect on our analysis should be noted. For example, whereas quadrupling the risk for blacks occurs at the 17th percentile at term, doubling the risk would occur above the 25th percentile. Although surveillance for this extremely large group may become realistically feasible in the future, we believe it impractical to provide reasonable fetal surveillance to the group based on current capabilities.

Fig. 4 shows a compilation of our data that is useful for patient management. It incorporates not only the racial differences in birth weights but also the racial differences in sensitivity to altered growth. Most importantly, the *actual* birth weight resulting in quadrupling the stillbirth rate can be determined. At 40 weeks' gestation, a white infant weighing <2950 gm (6 pounds, 8 ounces), or a black infant weighing <2800 gm (6 pounds 3 ounces) has greater than four times the risk of stillbirth compared with their more appropriately grown peers. These weights are substantially *above* weights generally perceived as small by the obstetric or pediatric providers. When compared with the Denver 10th percentile (as shown in Fig. 4), these "risk weights" average 400 to 500 gm *above* the weight generally perceived to represent risk. If these race-specific risk curves replace currently used data sets, the potential for identifying a significant portion of fetuses at risk for stillbirth will be enhanced.

Effects of intravascular fetal blood transfusion on fetal intracardiac Doppler velocity waveforms

Giuseppe Rizzo, MD,[a] Kypros H. Nicolaides, MD,[b] Domenico Arduini, MD,[a] and Stuart Campbell, MD[b]

Rome, Italy, and London, England

In 12 fetuses from pregnancies with red blood cell isoimmunization Doppler velocity waveforms were recorded at the level of atrioventricular valves immediately before and at 15-minute intervals for 2 hours after the intravascular transfusion. The left and right cardiac outputs, the ratio between the peak velocities during early passive ventricular filling and active atrial filling at the level of both ventricles as well as the heart rate were calculated. Before transfusion, the left and right cardiac outputs were significantly higher than reference ranges for gestation that were constructed from the cross-sectional study of 187 normal pregnancies. After transfusion there was a significant temporary fall in right and left outputs associated with increased ratios between the peak velocities during early passive ventricular filling and active atrial filling. Within 2 hours after transfusion both parameters returned toward the normal range. In addition, no significant changes were found for fetal heart rate values before and after transfusion. The fall of cardiac output was significantly related to the amount of expansion of the feto-placental volume. (Am J Obstet Gynecol 1990;163:1231-8.)

Key words: Red blood cell isoimmunization, intrauterine intravascular transfusion, cordocentesis, fetal echocardiography, Doppler ultrasonography

Intravascular fetal blood transfusion by cordocentesis represents a significant improvement in the treatment of red blood cell isoimmunization.[1] However, to limit the risks of repeated procedures and to shorten the duration of the transfusion the amount of blood transfused is usually high with respect to the estimated fetoplacental blood volume and is injected rapidly.

Up to now few data are available on the effects of such treatment on fetal hemodynamics.[3, 4] The advent of Doppler echocardiography has made it possible to study intracardiac blood flow velocity waveforms in the human fetus and to obtain reliable assessment of cardiac output.[5, 6] We therefore examined the effect of intravascular blood transfusion on cardiac hemodynamics in a group of fetuses from pregnancies with red blood cell isoimmunization.

Material and methods

Twelve pregnancies complicated by red blood cell isoimmunization undergoing intravascular transfusion were considered for this study. All pregnancies were singleton and accurately dated by certain last menstrual period and early ultrasonographic examination. All the fetuses had been previously transfused and the time interval from the preceding transfusion ranged between 2 and 4 weeks. The criteria followed for the timing of transfusions has been reported in detail elsewhere.[1] Although none of the fetuses had ultrasonographic evidences of hydrops, in all the cases the fetal hemoglobin concentration was below the second SD (mean difference, −3.62 SD; range, −2.43 to −5.16 SD) of our reference range for gestation.[7]

The mean (± SD) gestational age at the time of the study was 31.42 ± 3.18 weeks (range, 26 to 37). Before transfusion all patients gave their informed consent to participate in the study.

Doppler recordings. Commercially available Acuson 128 color Doppler equipment (Acuson, Montain View, Calif.) with 3.5 or 5 MHz sector probes was used for all measurements. Recordings were performed with the mother lying in a comfortable semirecumbent position. All the recordings were performed by one operator (G. R.) and the technique used has been reported in detail.[8] Briefly, an apical four-chamber view of the fetal heart was first obtained. The color flow mapping function was then superimposed and the transmitral and transtricuspid flow observed. The sample volume was placed immediately below either the mitral or tricuspid valves in the point of maximum flow velocity, as ex-

pressed by the color brightness, and velocity waveforms were then recorded. Doppler and two-dimensional images were recorded on standard ½-inch videotape for subsequent analysis. Recordings were performed immediately before (0) and at 15-minute intervals for 2 hours after the intravascular transfusion (+15, +30, +45, +60, +75, +90; +105, +120). Recordings obtained with an angle of insonation >30° or during periods of fetal body and breathing movements were rejected.

Atrioventricular valve diameters were evaluated from the two-dimensional images obtained from optimal apical four-chamber views. Measurements were performed in playback on video-recorded images frozen during diastole when showing the maximized diameters. Measurements were repeated on 10 different cycles for each valve and the values obtained were averaged. Repeated diameter measurements varied <0.6 mm for either valve. Valvular area was calculated assuming a circular cross-section.

Permanent records of all the velocity waveforms were obtained from the videotape by means of a strip chart recorder. The printouts were labeled with random numbers. The observer involved in the later analysis was not informed of the sequence of the printouts. Ten consecutive velocity waveforms were selected for each time interval from both atrioventricular valves and measurements of the following variables were made by use of the digitizing tablet of a computer (Cardio 800, Kontron, Oxford, England): (1) peak velocities during early ventricular filling (E wave) and atrial contraction (A wave); (2) mean temporal velocity; (3) fetal heart rate.

For each time interval a ratio between E peak and A peak velocities (E/A ratio) at the level of both atrioventricular valves was calculated. Absolute right and left cardiac outputs (milliliters per minute) were derived by multiplying the tricuspid or mitral mean temporal velocities, valvular area, and heart rate. The ratio between right and left cardiac output was then calculated. Cardiac output was also expressed as milliliters per minute per kilogram. The fetal weight was estimated from the ultrasonographic measurements of fetal biparietal diameter and abdominal circumference[9]; in all the cases abdominal circumference values ranged between the 10th and 90th percentile of our reference limits.

The data of the fetuses with red blood cell isoimmunization were compared with reference ranges constructed on the cross-sectional study of 187 fetuses from normal pregnancies between 20 and 40 weeks' gestation.

In our laboratory the intraobserver coefficient of variation for all the measurements considered is <12%.

Method of transfusion. Intravascular fetal blood transfusion was performed in accordance with a previously described technique without maternal sedation or fetal paralysis.[1] The site and direction of the umbilical cord at its placental insertion was defined by real-time ultrasonographic scanning and a 20-gauge needle was inserted in the umbilical vein. A 2 ml sample of fetal blood was aspirated for measurement of hemoglobin (Coulter S Plus counter, Coulter Electronics Ltd., Luton, England) and blood gases (ABL 30 blood gas analyser, Radiometer, Copenhagen, Denmark). Fetal transfusion was performed with packed red blood cells compatible with the mother (mean hematocrit, 73.43%; SD, 7.18%; range, 63.0% to 87.8%). At the end of the transfusion the needle was flushed with normal 0.5 ml of saline solution and after 1 minute a sample of fetal blood was aspirated. The first 0.5 ml were discarded and the posttransfusion hemoglobin and hematocrit were subsequently evaluated.

The fetoplacental volume was determined as previously reported[2] and the percentage of its expansion after the transfusion was calculated: % Expansion = (Blood volume transfused/fetoplacental blood volume) × 100. Furthermore, we evaluated the expansion rate: (Expansion rate = Transfusion rate/fetoplacental blood volume) × 100.

Statistical analysis. The changes of E/A ratios, left cardiac output, right cardiac output, and heart rate were evaluated as the percentage change from the values obtained before transfusion (basal values). Data obtained at each time interval were averaged and reported as mean values ± 1 SD. Statistical analysis was performed with the use of analysis of variance for repeated measurements and the paired and unpaired student *t* test as indicated in the text. Relationships between the variables considered were tested by stepwise regression analysis. These analyses were performed on a Macintosh II computer with the Stat View II statistical package (Abacus Concepts Inc., Berkeley, Calif.).

Results

Intravascular transfusion was successful in all the fetuses studied and the individual hematologic values measured before and after transfusion are shown in Table I. Blood gas analysis performed before transfusion revealed P_{O_2}, P_{CO_2}, and pH values within 95% confidence interval of our reference ranges for gestation.[11]

Reliable recordings of right cardiac output and left cardiac output were obtained respectively 93.5% and 90.7% of the cases.

The prefusion values of left cardiac output, right cardiac output, and ratio of right cardiac output to left cardiac output of the fetuses with red blood cell isoimmunization are plotted on our reference ranges for gestation (mean and 95% confidence intervals) in Fig. 1. After correction for fetal weight the right cardiac output and left cardiac output were significantly higher (the unpaired Student *t* test, $p \leq 0.01$) than in the control group (Table II). Furthermore there was a tendency for the E/A ratios of both atrioventricular valves to be higher than those in our normal controls (Fig. 2) but this did not reach statistical significance.

After transfusion the right cardiac output and left cardiac output fell. Subsequently there was an increase in both parameters but to less than pretransfusion values (Fig. 3). Analysis of variance demonstrated the significance of these changes for both right cardiac output [$F(10,100) = 16.13, p \leq 0.001$] and left cardiac output [$F(10,97) = 13.47, p \leq 0.001$]. Significant differences

were found (the paired Student t test) between pretransfusion values of right cardiac output and left cardiac output and +15, +30, +45, +60, +105, +120 values. Furthermore the E/A ratios were significantly modified after transfusion [tricuspid valve $F(10,100) = 8.21$, $p \leq 0.001$; mitral valve $F(10,97) = 4.59$, $p \leq 0.01$]. The highest value of E/A ratio were found at +15 minutes and then progressively returned toward basal values (Fig. 4).

No significant changes were found after transfusion for the ratio of right cardiac output to left cardiac output [$F(10,96) = 0.98$, NS] or fetal heart rate [$F(10,100) = 1.42$, NS]. The individual data obtained before and at the +15-, +30-, and +120-minute in-

tervals after intravascular transfusion are provided in Table III.

Stepwise regression analysis revealed a significant linear correlation between the percentage of expansion of the fetoplacental blood volume (independent variable) and the maximum individual percentage fall of combined cardiac output (left cardiac output + right cardiac output) after transfusion (dependent variable); $r = 0.77$, $p \leq 0.01$, slope = 0.22, intercept, −21.01. There were significant correlations between the other Doppler parameters measured and either the volume of blood transfused or the percentage of expansion or the rate of expansion of the fetoplacental blood volume.

Comment

Our findings of increased fetal cardiac output in pregnancies with red blood cell isoimmunization is in agreement with previous reports on both the animal and the human fetus.[11-13] Although the mechanisms that cause the increase of cardiac output are still unclear two main factors have been suggested in animals[11]: first, decreased blood viscosity leading to increased venous return and cardiac preload, and second, peripheral vasodilatation as a result of a fall in blood oxygen content and therefore reduced cardiac afterload.

Previous studies in red blood cell isoimmunization have shown an increase of blood flow velocities from different fetal peripheral vessels including umbilical vein,[14] descending aorta,[3, 4, 15] and common carotid artery,[4] and the increase of velocity was related to the severity of anemia. The high pretransfusion E/A ratios found in this investigation suggest that cardiac preload is increased.[13] Furthermore, because the right cardiac output to left cardiac output ratio was normal there is no evidence for a redistribution of cardiac output sim-

ilar to that described in hypoxic growth-retarded fetuses (i.e., the so-called "brain sparing effect").[7] These findings suggest that in red blood cell isoimmunization the changes in fetal cardiac output are mainly related to the low blood viscosity.

Intravascular fetal blood transfusion was associated with a rapid decrease in cardiac output that was primarily the result of decrease in stroke volume rather than heart rate. These changes were similar in both ventricles and reached a nadir at 15 to 45 minutes after the transfusion. Thereafter the cardiac output increased but still remained below the pretransfusion level.

These findings are compatible with the observations of Bilardo et al.[4] who measured the time-averaged mean velocity in the fetal descending thoracic aorta and common carotid artery before and within 30 minutes of intravascular transfusion and found a significant decrease in both vessels.

A possible explanation for posttransfusion decrease in cardiac output is reduced venous return to the heart secondary to the increased hematocrit and therefore viscosity of blood or secondary to the release of vasodilators such as prostacyclin or atrial natriuretic factor.[16, 17] However, this is unlikely because the relative E/A ratios found after the transfusion suggest that cardiac preload is increased rather than decreased. Furthermore, if the decrease in cardiac output was because of increased hematocrit, this effect would be sustained for at least 24 hours. Copel et al.[12] measured velocities in the aorta and also cardiac output at 12 hours after intravascular blood transfusion and found no significant differences from the pretransfusion levels. Finally, the reported increase of umbilical venous pressure after intravascular transfusion[18, 19] does not support the hypothesis of a venous vasodilatation as the cause of a reduction in venous return.

The alternative explanation for the posttransfusion fall in cardiac output is cardiovascular overload. This is supported by the findings of a direct relationship between the fall in cardiac output and the degree of expansion of the fetoplacental blood volume. Animal studies have shown that the fetal heart has very limited reserve capacity to increase its output in response to acute overload[18] and that massive increases in fetal blood volume are associated with a decrease in cardiac output.[19] After a transfusion there is a rapid rate of fluid loss[20] and this explains the rapid recovery in E/A ratios and cardiac output.

Doppler echocardiography provides a reproducible method for the measurement of cardiac output in the human fetus.[5, 6] However, this analysis is prone to errors mainly because of inaccuracies in the determination of valve diameters that are halved and squared in the calculation of cardiac output and thus amplified. Nevertheless in our investigation the flow orifice area is assumed to remain unmodified and therefore potential errors in assessment of valve diameters would affect similarly the measurements performed during the study without impairing the reliability of the results obtained.

In conclusion, fetal anemia is associated with increased cardiac output. Rapid intravascular blood transfusion causes a temporary and symmetrical decrease in right cardiac output and left cardiac output that is proportional to the degree of expansion in fetoplacental blood volume.

Human fetal foramen ovale flow velocity waveforms relative to behavioral states in normal term pregnancy

Jim van Eyck, MD, PhD, Patricia A. Stewart, PhD, and Juriy W. Wladimiroff, MD, PhD
Rotterdam, The Netherlands

In 16 normal pregnancies the relationship between foramen ovale flow velocity waveforms and fetal behavioral states at 37 to 38 weeks' gestation was studies with Doppler techniques. Foramen ovale flow velocity waveforms are characterized by a typical systolic/diastolic component. Average flow velocity was statistically significantly increased in behavioral state 2F (active sleep) as compared with state 1F (quiet sleep), which was mainly determined by an increase in flow velocity during the end-systolic and passive atrial filling phase. The increase in the average flow velocity at the foramen ovale level during active sleep suggests a redistribution of blood flow at the cardiac level, resulting in an increased right-to-left shunt. (Am J Obstet Gynecol 1990;163:1239-42.)

Key words: Human fetal behavioral states, foramen ovale flow velocity, fetal Doppler ultrasonography

In the normal growing human fetus at term blood flow velocity waveforms obtained from the lower thoracic part of the fetal descending aorta[1] and internal carotid artery[2] show fetal behavioral state dependency. In state 2F (active sleep) pulsatility index values in these vessels are significantly reduced as compared with state 1F (quiet sleep), reflecting reduced downstream impedence and suggesting increased perfusion of skeletal musculature and cerebrum during active sleep.[1, 2] At the cardiac level it was demonstrated that in the fetal ductus arteriosus peak flow velocity during behavioral state 2F is markedly reduced as compared with state 1F, suggesting a redistribution in left and right ventricular output in favor of the left side of the heart.[3]

In the normal fetus, inferior vena cava flow represents 65% to 70% of the total venous return to the heart,[4] approximately 40% of which is shunted to the left atrium through the foramen ovale. Behavioral state–related changes in foramen ovale flow could account for the suggested redistribution of ventricular output. With the introduction of combined realtime and Doppler systems the possibility became available to study blood flow velocity waveforms at the level of the foramen ovale. The objective of the present study was to investigate the relationship between blood flow velocity waveforms at the level of the foramen ovale and behavioral state 1F and 2F according to the classification of Nijhuis et al.[5] in the normal term fetus.

Material and methods

A total of 16 women with normal singleton pregnancies at 37 to 38 weeks' gestation gave consent to participate in the study. The gestational age had been calculated from a reliable menstrual history and early ultrasonographic measurement of fetal crown-rump length or biparietal diameter. Fetal birth weight was between the 10th and 90th percentile for gestational age, according to Kloostermans' tables, corrected for maternal parity and fetal sex.[6] All subjects were nonsmokers; no medications were prescribed. All studies were carried out 2 hours following after breakfast or lunch, with the study participants in the semirecumbent position. With a two-dimensional real-time mechanical sector scanner (Vingmed CFM 700, Sonotron, Horten, Norway; carrier frequency 3 MHz, Doppler 3 MHz with variable depth of sample gate and sample size) blood flow velocity recordings through the foramen ovale were made with either a four-chamber view or a modified short-axis view. In both views the valve of the foramen ovale could always be visualized. Color Doppler techniques were used in the first two participants but were subsequently abandoned as the central portion of the foramen ovale "defect" was clearly visualized with standard cross-sectional techniques. The sample gate was placed across the septal opening and the angle of insonation was always kept below 10°. Flow velocity waveforms at the foramen ovale level were obtained during behavioral states 1F and 2F, which were defined as follows:

State 1F: quiescence, which can be regularly interrupted by brief gross body movements, which mostly

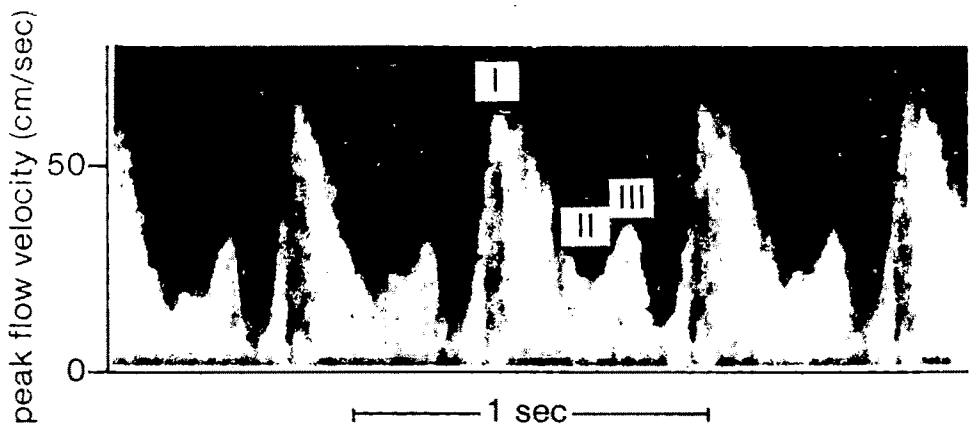

Fig. 1. Foramen ovale flow velocity waveforms *I* = systolic ventricular phase, *II* = end-systolic ventricular phase, and *III* = passive atrial filling phase.

are startles; eye movements absent and a stable heart rate pattern with a small oscillation bandwidth. Isolated accelerations do occur, but are strictly related to fetal movements.

State 2F: frequent and periodic gross body movements that are mainly stretches and retroflexions and movements of extremities; eye movements continually present and a heart rate pattern with a wider oscillation bandwidth than in state 1F and frequent accelerations during movements.

To establish these behavioral states the following parameters were simultaneously recorded: (1) fetal heart rate, which was obtained from a Doppler ultrasonographic cardiotocograph (Hewlett Packard 8040A, Boeblingen, Germany; carrier frequency 1 MHz); (2) fetal eye movements, which were studied from a transverse view of the fetal face with a two-dimensional real-time linear array scanner (Hitachi EUB-27, carrier frequency 3.5 MHz; and (3) fetal body movements, which were obtained from a sagittal view of the fetal trunk with a two-dimensional real-time and mechanical sector scanner (Vingmed CFM 700, carrier frequency 3 MHz).

The three transducers were placed in such a way that there was minimal interference between the three ultrasonographic modes. Flow velocity recordings were only performed when a clear fetal behavioral state was identified and when this state had been present over a period of at least 3 minutes. All recordings were performed during fetal apnea. The maximum amount of time for the completion of a flow velocity recording after a state determination was 3 minutes. The blood flow velocity waveforms were recorded on videotape. From hard copies of each recording, optimal flow velocity waveforms were selected. The foramen ovale waveform consists of two components (Fig. 1). During ventricular systole flow velocity reaches a maximum (I), after which it reduces in late systole (II). During the passive atrial filling phase corresponding with the E wave again there is an increase in flow velocity (III) that decreases with atrial contraction to zero (D. Soyeur et al. 1989, personal communication). With a microcomputer (Olivetti M24) flow velocities (centimeters per second) were calculated during the peak systolic (I), end-systolic (II), and passive atrial filling phase (III) of the cardiac cycle. Moreover, the average velocity (centimeters per second) and period time (cycle duration in milliseconds) were determined. To reject the null hypothesis that there is no difference in the individual paired differences of waveform components between behavioral state 1F and 2F, we used the two-tailed Student *t* test. Statistical significance was considered to be present if $p < 0.05$.

Results

Doppler signals could not obtained in two women because of anterior position of the fetal spine, leaving 14 women for further analysis. The mean number of blood flow velocity waveforms studied at the level of the fetal foramen ovale for all 14 women was 17 ± 8 (1 SD) in behavioral state 1F and 16 ± 5 (1 SD) in behavioral state 2F, resulting in a total number of 460 waveforms. Measurements of peak systolic, end-systolic, passive atrial filling phase, and average flow velocity showed considerable consistency reflected by the mean value of the SD of the individual measurements being 2.4, 1.6, 2.6, and 1.9 for behavioral state 1F and 3.1, 2.1, 2.4, and 1.8 for behavioral state 2F. The results of the paired analysis of the data in behavioral states 1F and 2F are presented in Table I. Average flow velocity was significantly ($p < 0.001$) increased in behavioral state 2F as compared with state 1F. This was mainly determined by an increase in flow velocity during the end-systolic and passive atrial filling phase of the foramen ovale flow velocity waveform (Fig. 2). No significant difference in period time could be established between behavioral states 1F and 2F.

Comment

Doppler ultrasonography allows visualization of blood flow through the foramen ovale and documentation of flow velocity waveforms through this cardiac shunt in the normal term fetus. During fetal development there are two major shunts at the cardiac level (i.e., the ductus arteriosus and the foramen ovale). In the fetal ductus arteriosus it was demonstrated that peak systole flow velocity is markedly reduced during behavioral state 2F as compared with state 1F, suggesting a redistribution in left and right ventricular output in favor of the left side of the heart.[3]

The results of the present study show that peak flow velocity through the foramen ovale is nearly twice as high during ventricular systole as compared with the diastolic phase. The increased foramen ovale flow during ventricular contraction may be explained by the fact that the closed tricuspid valve prevents superior vena cava blood flow from entering the right ventricle, leading to a raised right-to-left atrial pressure gradient. The upward movement of the tricuspid leaflets during ventricular contraction further contributes to this increased pressure gradient. Moreover, averaged flow velocities at the foramen ovale level are raised in behavioral state 2F. Because volume flow is equal to the average flow velocity multiplied by area, the increase in the average flow velocity could be a result of an increase in volume flow through the foramen ovale during active sleep. Inasmuch as the foramen ovale will open at an increased pressure gradient between the right and left atrium, one may speculate that flow velocity will be negatively influenced by the subsequent

increase in lumen area of the formen ovale. Therefore volume flow through the foramen ovale may be even larger than the rise in flow velocity would suggest. The described flow changes at the foramen ovale level are in agreement with the behavioral state–dependent flow changes documented in the ductus arteriosus[3] in that they suggest that in the normal term fetus the active sleep state is associated with preferential flow to the left side of the heart. Elevated average flow velocities at the foramen ovale level are mainly determined by the end-systolic and passive atrial filling phase of the flow velocity waveform, suggesting increased passive atrial filling during diastole as a result of a raised preload. This would be in agreement with Teitel et al.[7] who showed that during fetal development venous return (preload) can be raised by an increased preferential streaming of umbilical venous blood through the ductus venosus into the inferior vena cava, by-passing the hepatic microcirculation.

It can be concluded that in the normal term fetus the foramen ovale plays an important role in behavioral state–dependent redistribution of blood flow at the cardiac level.

Suppression of serum insulin level by diazoxide does not alter serum testosterone or sex hormone–binding globulin levels in healthy, nonobese women

John E. Nestler, MD,[a] Roshnara Singh, MD,[a] Dennis W. Matt, PhD,[b] John N. Clore, MD,[a] and William G. Blackard, MD[a]

Richmond, Virginia

Suppression of serum insulin levels with diazoxide is associated with a decrease in serum testosterone and an increase in serum sex hormone–binding globulin in obese women with the polycystic ovary syndrome. To determine whether physiologic insulin levels play a regulatory role in the androgen status of nonobese women with normal menses, the androgen status of five nonobese normal women was assessed on two occasions: during a control study and after 10 days of oral diazoxide (100 mg, three times daily) administration. Insulin release in response to 100 gm oral glucose administration decreased from 108.0 ± 28.2 to 49.3 ± 5.2 nmol · min/L ($p = 0.05$) after diazoxide administration. However, despite suppression of insulin release, diazoxide administration did not affect serum total testosterone (diazoxide, 0.73 ± 0.10; control, 0.69 ± 0.11 nmol/L; p = NS) or sex hormone–binding globulin (diazoxide, 79.7 ± 16.6; control, 70.2 ± 12.6 nmol/L; p = NS) concentrations. These observations suggest that physiologic insulin levels in nonobese healthy women do not regulate testosterone metabolism and that diazoxide does not exert a direct or independent effect on serum testosterone or sex hormone–binding globulin levels. (Am J Obstet Gynecol 1990;163:1243-6.)

Key words: Polycystic ovary syndrome, testosterone, insulin resistance, androgens, hyperinsulinemia

The hyperandrogenism of some women with the polycystic ovary syndrome may result from hyperinsulinemia.[1] In support of this view we recently demonstrated that suppression of serum insulin levels with diazoxide is associated with a fall in serum testosterone levels and a rise in serum sex hormone–binding globulin levels in obese women with the polycystic ovary syndrome.[2] However, it remains unknown whether physiologic insulin levels play a regulatory role in the androgen status of nonobese women with normal menses or whether diazoxide itself might directly affect androgen homeostasis. To address these issues, we assessed the androgen status of five nonobese healthy women during a control period and after suppression of serum insulin levels with diazoxide.

Material and methods

Study design. Eight women were initially enrolled into the study but three women withdrew before completion because of side effects of diazoxide (diffuse edema, palpitations, anxiety). The remaining five women were between 23 and 39 years old and nonobese (body mass index values ranged from 18.5 to 24.5 kg/m^2). Each woman was healthy, had a normal menstrual history, and was not taking any medications. The study was approved by the Committee on the Conduct of Human Research of the Medical College of Virginia, and signed informed consent was obtained from each subject.

All subjects were studied in the follicular phase of the menstrual period (between days 5 and 9 after onset of menses). Two subjects were studied during a control period and once again 28 days later after having taken 100 mg diazoxide orally three times daily (300 mg/day) for 10 days. The remaining three subjects were studied in the reverse order. The subjects were allowed to eat at will, and the last dose of diazoxide was taken on the morning of study.

The control study and the study after diazoxide administration were conducted in an identical manner. The women were admitted to the General Clinical Research Center of the Medical College of Virginia after

an overnight fast. Weight and height were recorded, and a heparin lock was inserted into a hand vein for blood withdrawal. Blood samples were drawn at 8, 8:15, and 8:30 AM, and the sera were pooled for determination of serum steroid, sex hormone–binding globulin, and gonadotropin concentrations. To determine the efficacy of diazoxide in inhibiting insulin release, the women drank 100 gm of glucose (Glucola, Whitaker General Medical, Richmond, Va.) at 8:30 AM, and blood samples were drawn every 15 minutes from 8:30 to 11:30 AM for determination of serum glucose and insulin levels.

Assays. Serum glucose concentrations were determined by the glucose oxidase method (Beckman Glucose Analyzer 2, Fullerton, Calif.). Serum insulin levels were determined by radioimmunoassay.[3] The intraassay coefficient of variation for the insulin assay was 5.0%. The integrated insulin response during the oral glucose tolerance test was analyzed by calculating the area under the curve for insulin during the 3 hours after glucose ingestion by the trapezoidal rule using absolute values.

Serum testosterone, androstenedione, estrone, 17β-estradiol, and progesterone concentrations were measured by radioimmunoassay as previously described.[2, 4] Serum (1.0 ml) was extracted with diethyl ether, and steroids were isolated by Celite column chromatography. Highly specific antisera were used to measure testosterone, androstenedione, estrone, 17β-estradiol, and progesterone. Tritium-labeled steroids were added to serum before extraction to correct for procedural losses. The antiserum to testosterone was provided by Dr. Gordon Niswender (Department of Physiology, Colorado State University, Fort Collins, Colo.), and the antisera to androstenedione, 17β-estradiol, and progesterone were provided by Dr. John Resko (Department of Physiology, University of Oregon School of Medicine, Portland, Ore.). Antiserum to estrone was purchased from Steranti Research Ltd. (London). The intraassay coefficients of variation for all the steroid assays were <8.0%. Serum sex hormone–binding globulin concentrations were determined by an immunoradiometric assay with a commercial kit (Diagnostic Products, Los Angeles), and the intraassay coefficient of variation was 2.5%. Serum luteinizing hormone and follicle-stimulating hormone concentrations were determined by radioimmunoassay (Pacific Biotech, San Diego). The intraassay coefficients of variation of luteinizing hormone were 10.4% for 5 to 8 IU/L, 12.1% for 8 to 11 IU/L, and 6.6% for 11 to 35 IU/L. The intraassay coefficient of variation of follicle-stimulating hormone was 6.5%.

Glucose, gonadotropin, and sex hormone–binding globulin measurements from each woman were determined in duplicate in single assays.

Statistical analysis. All results are reported as the mean ± SE. All results were first tested for normality with the Wilk-Shapiro test and were then analyzed by Student's two-tailed paired t test. A value of $p < 0.05$ was considered significant.

Results

Mean body mass index increased by 0.8 kg/m² in the five women during diazoxide administration (diazoxide, 22.4 ± 1.3 kg/m²; control, 21.6 ± 1.3 kg/m²; $p < 0.015$), most likely as a result of fluid retention. In four women pretibial edema developed while they were taking diazoxide. Body mass index values returned to baseline shortly after cessation of diazoxide administration.

During the control study the women demonstrated normal glycemic and insulin responses during the oral glucose tolerance test (Fig. 1). Diazoxide administration uniformly decreased insulin release (area under the curve for insulin: diazoxide, 49.3 ± 5.2 nmol · min/L; control, 108.0 ± 28.2 nmol · min/L; $p = 0.05$) and caused deterioration of glucose tolerance (Fig. 1). Diazoxide administration did not significantly alter mean fasting serum insulin (diazoxide, 76 ± 25 pmol/L; control, 115 ± 19 pmol/L; p = NS) or glucose (diazoxide, 5.4 ± 0.4 mmol/L; control, 4.5 ± 0.1 mmol/L; p = NS) concentrations.

Diazoxide administration did not affect serum total testosterone or sex hormone–binding globulin concentrations (Table I). Diazoxide administration also did not alter serum androstenedione, estrone, 17β-estradiol, progesterone, luteinizing hormone, or follicle-stimulating hormone levels (Table I).

Comment

Hyperinsulinemic insulin resistance may be the cause of hyperandrogenism in some women with the polycystic ovary syndrome.[1] In support of this hypothesis, insulin resistance and elevated serum insulin levels have been well documented in women with the polycystic ovary syndrome.[5-7] This insulin resistance does not appear to be solely a result of the obesity often associated with the polycystic ovary syndrome because nonobese women with the polycystic ovary syndrome also manifest hyperinsulinemic insulin resistance.[7, 8]

To examine the role of chronic hyperinsulinemia on androgen levels in this disorder, we previously used diazoxide to reduce serum insulin levels in obese women with the polycystic ovary syndrome.[2] Diazoxide treatment uniformly suppressed glucose-stimulated insulin release and resulted in a significant reduction in serum testosterone concentrations. Serum sex hormone–binding globulin levels rose in all subjects. Since gonadotropin release did not change as a result of diazoxide administration, these results support the

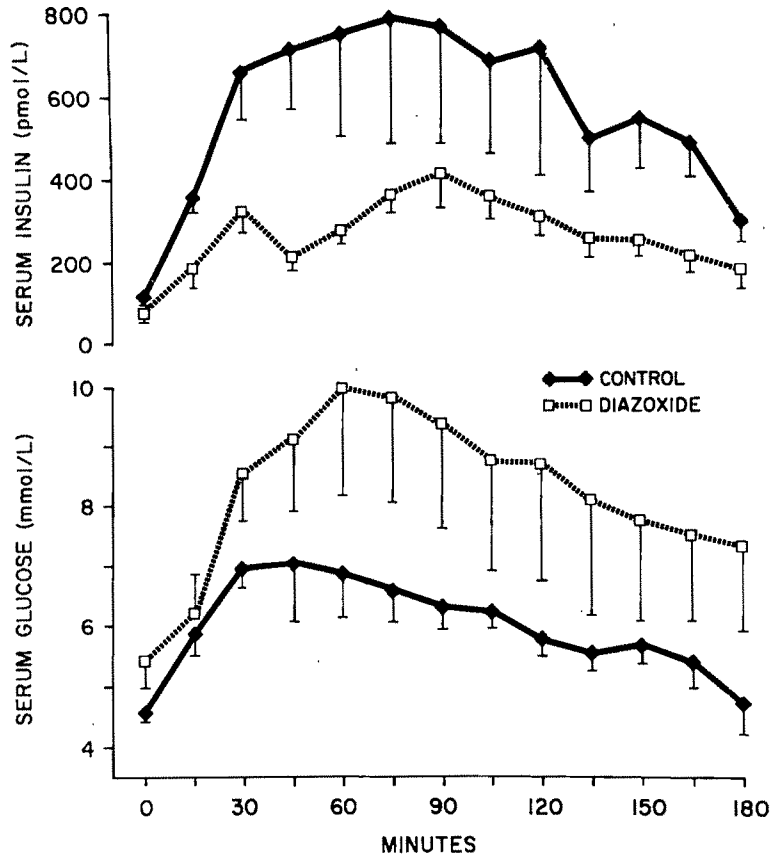

Fig. 1. Mean (± SE) serum glucose and insulin responses after 100 gm of oral glucose in five nonobese normal women during the control study *(closed circles)* and after 10 days of oral diazoxide (300 mg/day) administration *(open boxes)*.

Table I. Serum steroid, gonadotropin, and sex hormone–binding globulin concentrations in five nonobese, normal women at the time of the control study and after 10 days of oral diazoxide (300 mg/day) administration

	Control	*Diazoxide*	*p Value*
Testosterone (nmol/L)	0.69 ± 0.11	0.73 ± 0.10	0.71
Androstenedione (nmol/L)	3.5 ± 0.4	3.5 ± 0.3	0.96
Estrone (pmol/L)	296 ± 29	456 ± 56	0.09
17β-Estradiol (pmol/L)	270 ± 49	288 ± 42	0.40
Progesterone (nmol/L)	0.16 ± 0.03	0.09 ± 0.03	0.20
Luteinizing hormone (IU/L)	12.0 ± 1.1	11.2 ± 1.5	0.66
Follicle-stimulating hormone (IU/L)	9.7 ± 0.4	10.3 ± 0.9	0.62
Sex hormone–binding globulin (nmol/L)	70.2 ± 12.6	79.7 ± 16.6	0.24

Values represent mean ± SE.

hypothesis that hyperinsulinemia can directly affect testosterone metabolism.

In marked contrast, neither serum testosterone nor sex hormone–binding globulin levels changed in this study when serum insulin levels of nonobese healthy women were suppressed with diazoxide. These observations suggest either that normal women are not as sensitive to actions of insulin on androgen homeostasis as are women with the polycystic ovary syndrome or that insulin concentrations in the physiologic range do not play an important role in regulation of serum testosterone levels. Although the number of subjects in this study equaled the number of obese women with the polycystic ovary syndrome previously examined,[2] it remains possible that the negative results of this study were a result of the limited number of subjects.

In support of the possibility that normal women are not as sensitive to the androgenic actions of insulin as

are women with the polycystic ovary syndrome, evidence exists suggesting that androgenic pathways of normal women may be less responsive to stimulation by insulin than those of women with the polycystic ovary syndrome. Ovarian tissues removed from women with hyperandrogenism exhibit enhanced androstenedione and testosterone release in response to insulin, whereas ovarian tissues removed from normal women remain unaffected by insulin treatment.[9] This disparity also was noted in an in vivo study that demonstrated various effects of suprapharmacologic hyperinsulinemia on sex steroid concentrations of women with the polycystic ovary syndrome but not in normal women.[10]

Alternatively, it has been postulated that in the polycystic ovary syndrome elevated serum insulin levels affect androgenic pathways by cross reacting with the insulin-like growth factor-I receptor.[11] Insulin concentrations in the physiologic range may be too low to significantly associate with insulin-like growth factor-I receptors. Thus insulin may not regulate serum androgen levels under physiologic conditions.

Finally, these observations also indicate that diazoxide does not directly affect serum testosterone or sex hormone–binding globulin levels in vivo. Thus the androgen changes observed when diazoxide is administered to obese women with the polycystic ovary syndrome[2] are indeed a result of suppression of insulin release and are not an independent effect of diazoxide.

In summary, suppression of serum insulin levels by diazoxide in nonobese healthy women does not affect serum testosterone or sex hormone–binding globulin levels. These observations suggest that physiologic insulin levels in normal women do not regulate androgenic processes.

We thank the staff of the General Clinical Research Center of the Medical College of Virginia; Ms. Bettie Duke, CLINFO systems analyst; and Dr. Vernon Chincilli of the Department of Biostatistics for their help.

Intrapartum uterine rupture and inflammatory bowel disease

Ila M. Peterson, MD, and Bev Braak, MD
Kansas City, Missouri

The incidence of uterine rupture in pregnant women ranges from 0% to 1.1% in large series. This case report describes a woman with a history of obstetric complications, uterine rupture, and active inflammatory bowel disease that was treated with high-dose prednisone. (AM J OBSTET GYNECOL 1990;163:1247-8.)

Key words: Uterine rupture, inflammatory bowel disease, prednisone

Case report

A 24-year-old white woman (gravida 4, para 1-0-1-1) had a 10-year history of active Crohn's disease treated with 40 to 60 mg of prednisone daily. She was seen at 33 weeks' gestation (by dates and ultrasonography) complaining of nausea, vomiting, diarrhea, and contractions for several days. This pregnancy had been complicated by several admissions for exacerbation of regional enteritis and preterm labor. A previous pregnancy 13 months earlier resulted in a classic cesarean section at 27 weeks' gestation for abruptio placentae; the infant did not survive. In 1984 the patient was vaginally delivered of a premature infant at 34 weeks' gestation; that child is alive and well. Past surgical history was significant for colonic and partial small bowel resection in 1984 for Crohn's enteritis. The patient also had documented iron-deficiency anemia and marasmus malnutrition on multiple previous hospital admissions.

On admission the patient was pale and listless but her vital signs were normal. She had a right-sided draining perianal fistula and multiple perianal scars. The cervix was dilated to 1 cm and thick. Fetal heart tones were reactive and without decelerations. Contractions every 2 to 4 minutes were present on monitor; they failed to resolve after administration of intravenous ritodrine and only gradually decreased in frequency with use of magnesium sulfate. A bedside scan showed fetal breech presentation and an anterior placenta. By the fourth hospital day, the patient was given oral ritodrine without incident; the perianal fistula had improved after treatment with metronidazole (Flagyl, Searle & Co., Chicago). On the seventh hospital day the patient had mild regular contractions unchanged by hydration and sedation. She suddenly experienced severe, relentless abdominal pain; the abdomen grew tense and tender, and there was a small amount of blood present in the vagina. Fetal heart tones dropped from the range of 140 beats/min to the range of 80 beats/min and were unresponsive to oxygen and position change. An immediate cesarean section was performed for suspected abruptio placentae. The fetus was in its intact amniotic sac in the abdominal cavity. The anterior wall of the uterus was ruptured vertically in the midline and dark clots were seen at the margins of the myometrial wound. A 1788 gm male infant with Apgar scores of 0 at 1 minute and 3 at 5 minutes and a venous cord pH of 6.84 was delivered. Subsequently a total abdominal hysterectomy was performed. Mother and child were discharged in good condition on postoperative day 18.

The uterus with attached cervix weighed 435 gm. A large anterior vertical 10 cm uterine rupture was present and its margins were thick and hemorrhagic. The dehiscence was 6 cm wide. The uterine fundal wall was 3 cm thick and the region of the lower uterine segment was markedly thinned to 5 mm. Multiple sections through the area of the ruptured anterior wall showed focal hyalinization of smooth muscle, no necrosis, and no granulation tissue. Dense scarification was absent. Sections of the 1.2 cm, patent, intact cervix showed widespread human papillomavirus effect and moderate dysplasia. The discoid placenta was complete and weighed 407 gm, its trivesseled umbilical cord was eccentrically inserted and the placental membranes were cloudy gray. The maternal surface was covered with blood clot and the fetal surface was distorted by several cystic spaces filled with gelatinous pink, translucent material. Early acute chorionitis, small placental infarcts, and fibrin pools were present microscopically.

Comment

When idiopathic inflammatory bowel disease is active and severe at the time of conception, spontaneous abortion, stillbirth, or premature delivery are more likely.[1] Sulfasalazine and steroids should be used for idiopathic inflammatory bowel disease in the pregnant woman

much as they are in the nonpregnant woman.[2] There is no firm evidence that use of sulfasalazine has any harmful effects on the fetus. However, it is advisable to maintain the daily dose of prednisone below 20 mg/day when possible because some reports have suggested an increase in stillbirths, reduction in birth weight, cleft palate, harelip, and finger anomalies associated with higher doses.[2] In this case the patient was steroid dependent and experienced severe exacerbation of her disease when steroids were withdrawn. The other effects of steroids are well documented: impaired inflammatory response, delayed wound healing, and muscle atrophy. These effects could prevent uterine sections from properly healing and thereby render the uterine wall incompetent. Dense scar could not be demonstrated in multiple sections of the ruptured uterus in this case. Previous cesarean section, both transverse and vertical, abruptio placentae, grand multiparity, previous curettage, manual removal of placenta or obstructed labor, oxytocin, epidural anesthesia, puerperal infection, and diethylstilbesterol exposure are factors known to predispose women to uterine rupture. In patients with uterine dehiscence (separation of uterine scar without rupture of the membranes), perinatal outcome is excellent. The number of previous cesarean sections, interval after previous cesarean section, placental localization, or ultrasonographic assessment do not predict the likelihood of uterine rupture for any one patient.

Maternal serum Down syndrome screening: Free β-protein is a more effective marker than human chorionic gonadotropin

James N. Macri, PhD,[a] Ramana V. Kasturi, BE, MS,[a] David A. Krantz, BS,[a] Edward J. Cook, PhD,[a] Norman D. Moore,[a] Jean A. Young,[a] Kathleen Romero, BS,[a] and John W. Larsen, Jr., MD[b]

Carle Place, New York, and Washington, D.C.

The use of quantitative human chorionic gonadotropin measurement in obstetrics has a long and successful history. Prior studies on the utility of human chorionic gonadotropin in Down syndrome screening have utilized assays that measure the intact human chorionic gonadotropin molecule. This study targeted a distinct marker, the human chorionic gonadotropin free β-protein, which is present in second-trimester maternal serum at much lower concentrations than is intact human chorionic gonadotropin. Our study of 29 cases of trisomy 21 and 450 control samples shows 80% detection efficiency with maternal serum α-fetoprotein, the free β-protein, and maternal age in pregnancies under 17 weeks' gestation. We conclude that the combination of maternal serum α-fetoprotein and the human chorionic gonadotropin free β-protein will be useful in the prenatal detection of trisomy 21. (Am J Obstet Gynecol 1990;163:1248-53.)

Key words: Screening, Down syndrome, free β-protein

The measurement of human chorionic gonadotropin (hCG) in maternal serum is under investigation as a biochemical marker for pregnancies at increased risk for trisomy 21. Human chorionic gonadotropin (hCG) is a complex glycoprotein produced by the placenta shortly after implantation of the fertilized ovum into the uterine wall. The intact hCG molecule is a heterodimer, consisting of two noncovalently bound subunits designated as α-subunit and β-subunit (Fig. 1). The free α- and β-proteins are produced within the syncytiotrophoblast, and are known to exist in maternal serum. Free α is coded for by the same gene that produces α-subunits of luteinizing human hormone, follicle-stimulating hormone, and thyroid-stimulating hormone. The β-proteins in all of these hormones are

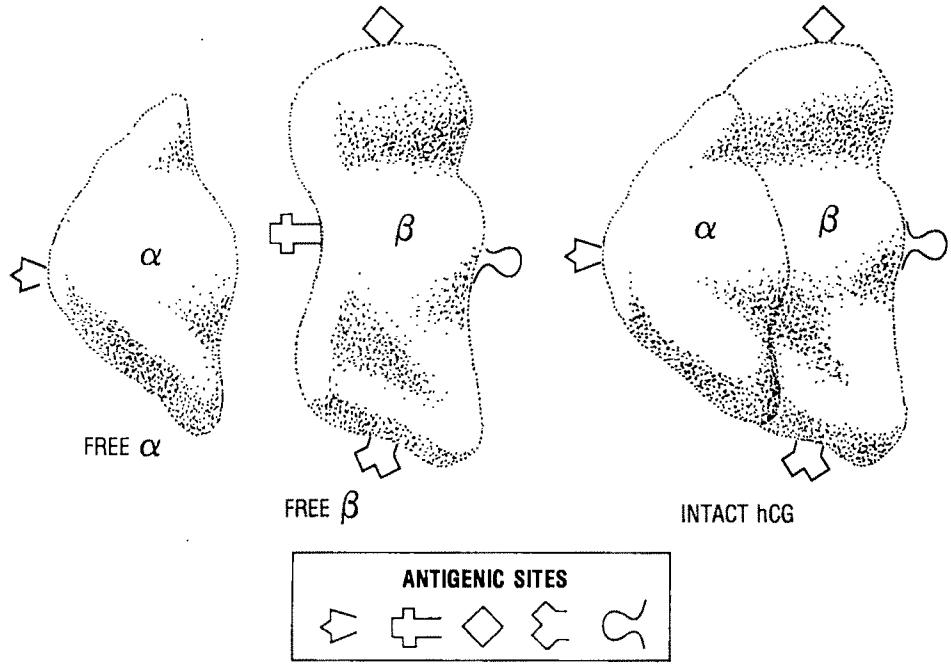

Fig. 1. Schematic representation of hCG molecule and its subunits.

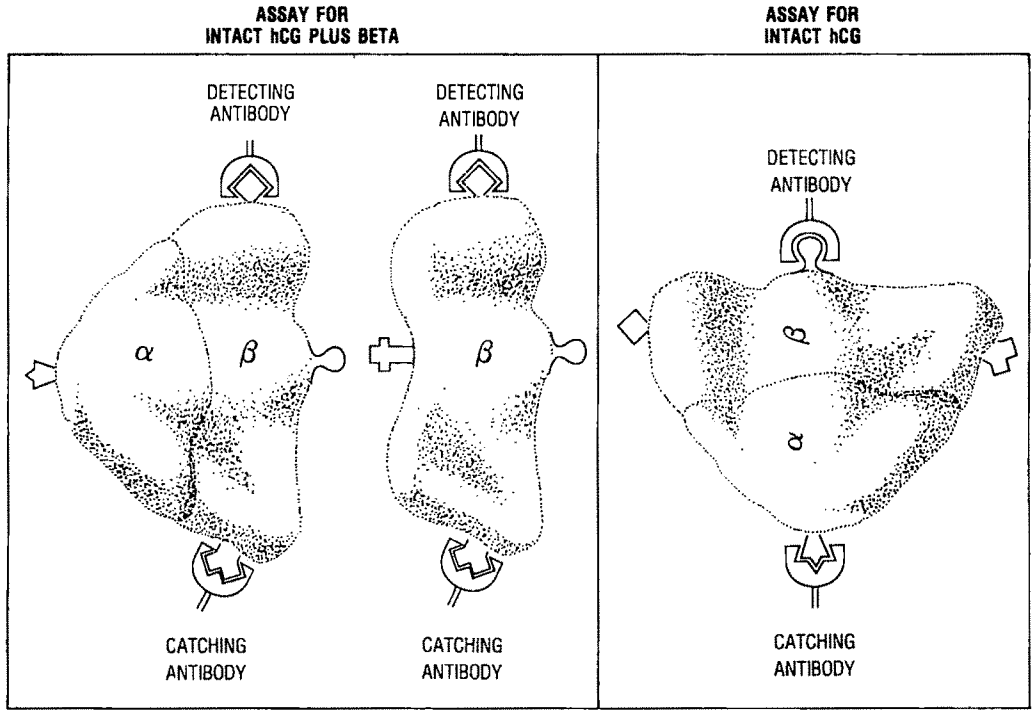

Fig. 2. Illustration of two-site immunoassays designed to measure (1) intact hCG plus free β-protein and (2) intact hCG alone.

coded for by distinct genes and display differing immunologic characteristics. In normal second-trimester maternal sera, intact hCG is found in levels ranging from 20,000 mIU/ml to 50,000 mIU/ml. In contrast, the levels of either free α- or free β-hCG are on average one half of 1% of intact hCG levels.[1]

Two methods are commonly used in measuring hCG (Fig. 2). The first measures intact hCG alone; the sec-

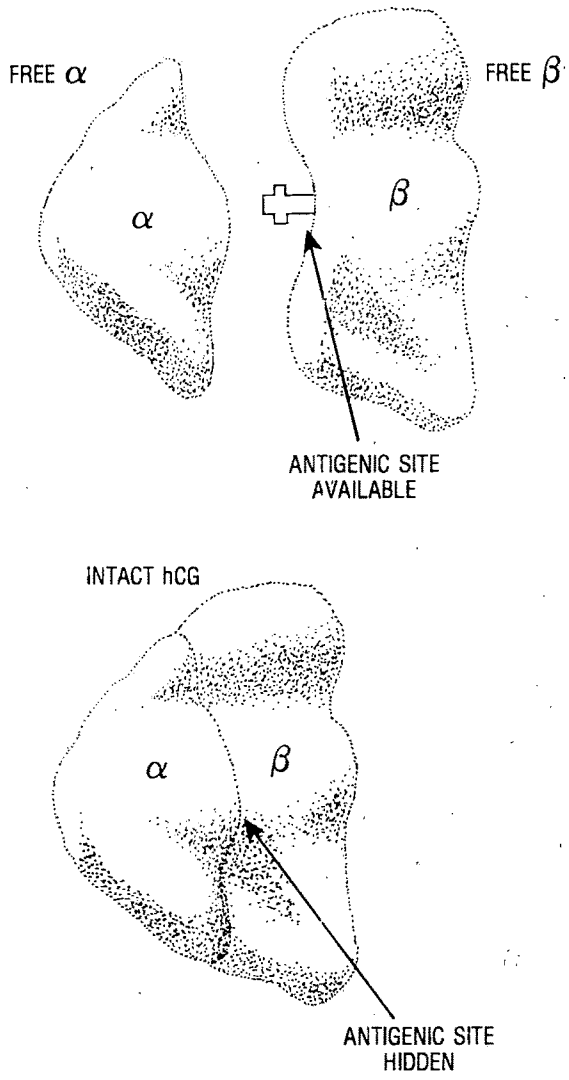

Fig. 3. Schematic representation of free β-protein antigenic site. Note its unavailability in intact hCG molecule.

ond measures intact hCG plus free β-protein. These methods are considered to be equivalent because the amount of free β-protein is quantitatively insignificant in comparison with intact hCG. However, in our laboratory, both of these assay methods, when investigated as to their potential to detect Down syndrome, yielded dissimilar results. This observation as well as the fact that free β is unique to hCG, led us to hypothesize that an assay directed specifically against the free β-protein might be efficient for Down syndrome screening.

Material and methods

Four hundred seventy-nine maternal sera from 29 cases of trisomy 21 and 450 controls were retrieved from frozen storage at NTD Laboratories. These samples were from singleton, nondiabetic, white gravid women. All outcome information on these samples was obtained via requests to physicians.

Table I. Median maternal serum free β-protein levels

Weeks' gestation	*Control (ng/ml)*	*Trisomy 21 (ng/ml)*
14-16	16.3	34.7
17-18	10.9	19.9

Table II. Maternal serum free β-protein levels in terms of multiples of median in 29 confirmed trisomy 21 cases

Multiples of median	*No.*	*% of Total*
0-1	5	17.2
1-2	9	31.0
2-3	5	17.2
>3	10	34.5

Assays. Maternal serum α-fetoprotein (AFP) was quantitated by an in-house enzyme-linked immunosorbent assay (ELISA). This ELISA is a polyclonal-monoclonal assay with an effective working range of 2 to 250 IU/ml of AFP. Standards were calibrated against the World Health Organization standard 72/225.

Free β-protein was quantitated by an in-house ELISA that is a monoclonal-polyclonal assay with an effective working range of 1.5 to 100 ng/ml of free β-protein. Interassay and intraassay variation (on trilevel quality control samples run 236 times) was found to be 4.3% and 5.8%, respectively. Standards were calibrated against the first international reference preparation (IRP 75/551).

In assaying for free β-protein (Fig. 3), antibodies must be directed specifically against an antigenic site that is exposed only when free beta exists in its unbound form (i.e., not combined with the α-subunit to form the intact hCG molecule). The specific free β-antibody used in our assay procedure does not react with any other antigenic site on the β-subunit of intact hCG or any antigenic site on the α-subunit. In addition, the assay procedure used in this study ensured that only free β was measured by introducing a thorough washing step after the initial capture of free β-protein. The washing step effectively removes any analyte not initially captured by the specific free β-antibody. Such a procedure removes from the assay the intact hCG molecules that predominate in second-trimester maternal sera.

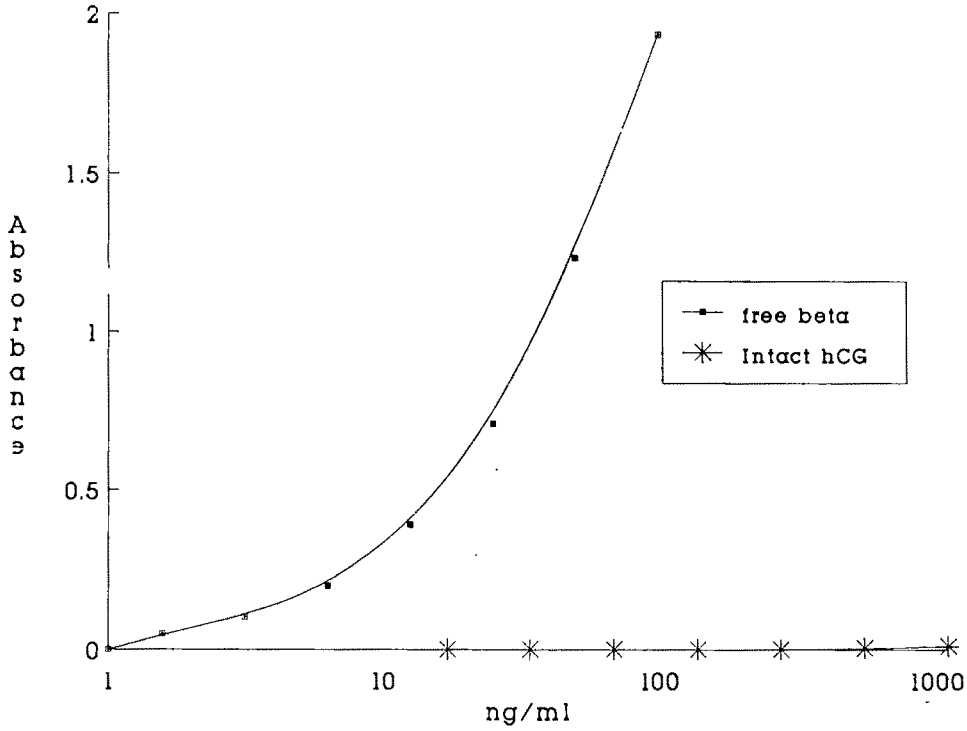

Fig. 4. Free β-protein assay absorbance values obtained with: (1) free β-protein standards and (2) serially diluted intact hCG standard from which free β-protein has been removed. Absence of cross-reactivity to intact hCG is demonstrated.

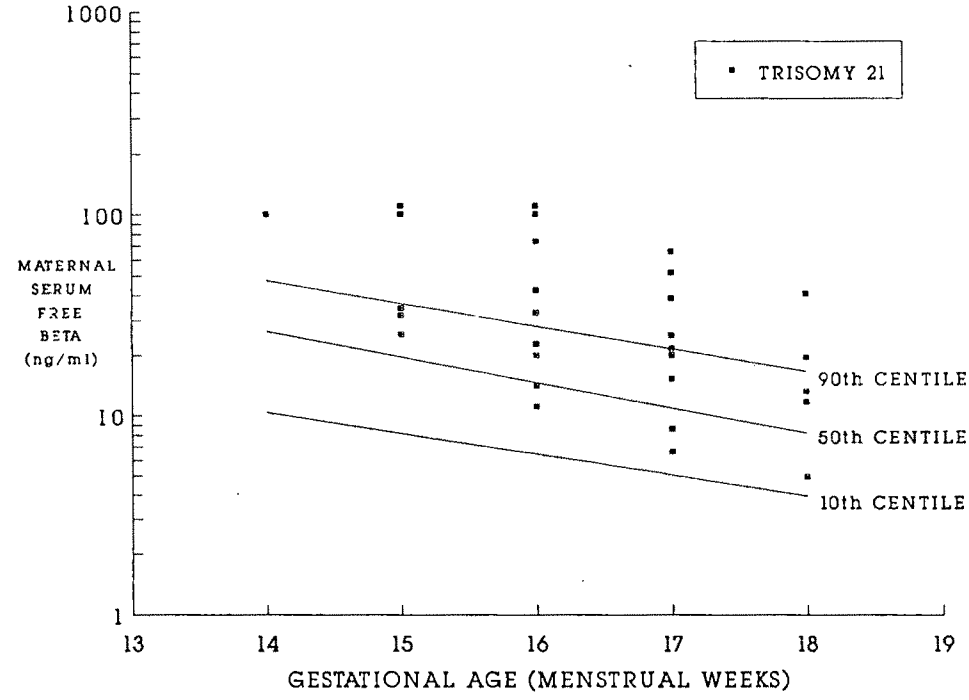

Fig. 5. Levels of free β-protein in cases of trisomy 21 in relation to 10th, 50th, and 90th percentiles of controls.

Table III. Trisomy 21 screening efficiency with free β-protein hCG alone and in combination with AFP at different gestational age ranges at 5% false-positive rate

Gestational age range (wk)	*No. of controls*	*No. of cases of trisomy 21*	*Detection efficiency of free β-protein (%)*	*Detection efficiency of AFP and free β-protein (%)*
<17	240	15	66.7	80
≥17	210	14	50.0	64.3
14-22	450	29	58.6	72.4

Proof of antigenic specificity to free β-protein was obtained by passing an intact hCG sample containing 1000 ng/ml over a free β-protein affinity chromatography column to effectively remove free β-protein. This sample (now void of free β-protein) was evaluated for cross-reactivity to intact hCG in our free β-protein assay. Fig. 4 demonstrates essentially no cross reactivity. This provides proof that our free β-antibody (and assay) does not react with epitopic sites on intact hCG but does react with epitopes that are exposed when free β-protein exists in its unbound state.

To determine detection efficiency and false-positive rates we used a linear, multivariate, discriminant analysis model. Gestational age was included as a variable in the model along with biochemical markers. The natural logarithm of the level of each analyte was used. Linear, multivariate, discriminant analysis was performed with the commercially available software package SAS (Statistical Analysis System, SAS Institute, Inc., Cary, N.C.). Population parameters (means, variances, and covariances) for each of the biochemical markers and gestational age were established for the cases of trisomy 21 and controls. The variances and covariances were pooled among the trisomy 21 cases and controls. Each patient's risk of trisomy 21 was calculated from Bayes' rule and the patient's maternal age-specific a priori risk.[2]

Results

As shown in Table I, a significant increase in the level of free β-protein was observed in trisomy 21 cases as compared with controls ($p < 0.0001$ using the Wilcoxon test). Fig. 5 illustrates the downward trend of free β-protein levels in controls by gestational age. Table II shows the distribution of the 29 trisomy 21 cases and reveals that 83% exceed the median of controls, and 52% exceed twice the median, for their respective gestational weeks.

Detection efficiencies for free β-protein alone and in combination with AFP are shown in Table III. Maximal detection efficiency was achieved by using maternal serum AFP and free β-protein at 14 to 16 weeks.

There was no trend in either maternal serum AFP or free β-protein levels with increasing maternal age for trisomy 21 cases or controls ($p = 0.24$ and 0.28 for maternal serum AFP, and $p = 0.85$ and 0.10 for free β-protein using Kruskal-Wallis analysis of variance for maternal serum AFP and free β-protein, respectively, across four different maternal age groups ≤26, 27 to 28, 29 to 31, and >31 years). Additionally, the correlation of the levels of free β-protein and maternal serum AFP was not significantly different from zero ($R = 0.11$, $p = 0.57$, and $R = -0.05$, $p = 0.28$ for trisomy 21 cases and controls, respectively).

Comment

The use of quantitative hCG measurement as a pregnancy test has had a long, straightforward, and successful history. However, use of commercially available hCG kits for prenatal Down syndrome screening is a more complex matter. Commercial kits that measure the intact hCG molecule plus free β-protein are often referred to as β-subunit hCG kits.[3] Superior detection efficiency in our study was achieved, not by measuring intact hCG in a so-called β-subunit hCG kit, but in fact by eliminating the intact hCG molecule through immunologic and assay washing procedures. Intact hCG plays no immunologic (and, by definition, no quantitative) role in what our assay measures. The analyte we measured is the free β-protein, which is a specific, independent marker present in second-trimester maternal sera at much lower concentrations than are intact hCG molecules (on average 1:200).

Our data show that quantitation of maternal serum free β has high predictive value (50% to 67%) for the serologic detection of trisomy 21. In fact, the use of an assay that measured only free β-protein produced a detection efficiency and false-positive rate comparable to that reported by some others using a combination of three assays.[4] In our study the highest rate of detection efficiency (80%) was achieved by combining analyses of free β-protein with maternal serum AFP. This combination appears to work optimally during weeks 14 through 16 of gestation, producing a detection efficiency of 80% with a 5% false-positive rate. Evaluation at even earlier weeks of gestation, when free β-protein levels are higher,[5] should be performed to determine whether further enhancement in detection efficiency results from such evaluation.

Whereas Bogart et al.[6] and Wald et al.[4] observed the

effectiveness of intact hCG as a marker for Down syndrome, the effectiveness of the free β-protein was not observed. By using assays specific to free β-protein, the analyte can be evaluated for its usefulness in Down syndrome screening. This was done in this investigation.

Conventional hCG assays that measure the intact hCG molecule require significant dilution of the sample (1/50 to 1/500) to bring the level of the analyte to a reasonable analytical range for measurement. There is no need for a predilution step in free β-protein assays. This represents an additional advantage from the perspective of assay development and use, as well as minimization of human error.

Our findings show that it is effective to include a combination of maternal serum AFP and free β-protein assays in a screening protocol for trisomy 21. The advantages of such a protocol include the following: (1) noninvasive techniques, (2) high detection efficiency with low false-positive rates, (3) simplified, undiluted free β-protein assays, (4) the use of markers that are essentially independent of one another, and (5) compatibility with current prenatal screening protocols.

Prenatal diagnosis of congenital cytomegalovirus infection by virus isolation from amniotic fluid

Carl P. Weiner, MD, and Charles Grose, MD

Iowa City, Iowa

Cytomegalovirus was isolated antenatally from the amniotic fluid of two pregnant women. In both cases prenatal diagnosis of the fetal virus infection aided the subsequent management of the mother and newborn infant. (AM J OBSTET GYNECOL 1990;163:1253-5.)

Key words: Cytomegalovirus, amniocentesis, prenatal diagnosis, congenital infection

In 1971 Davis et al.[1] published the first case of fetal cytomegalovirus infection diagnosed prenatally by isolation of the virus from amniotic fluid. The case report concerned a 17 year-old primigravid woman who was seen with a "mononucleosis-like syndrome" (fever, splenomegaly, thrombocytopenia, lymphocytosis) at 21 weeks' gestation. Amniotic fluid was aspirated by transabdominal amniocentesis, and cytomegalovirus was grown readily from the amniotic fluid. Since their report there has been some controversy concerning the use of amniotic fluid culture for the diagnosis of cytomegalovirus. We describe two additional cases of fetal cytomegalovirus infection diagnosed antenatally by isolation of the virus from amniotic fluid.

Case reports

Case 1. The patient was a 17-year-old white primigravid woman transferred to the University Hospital at 37 weeks' gestation. The pregnancy had been uncomplicated until the day before transfer when the patient had malaise, bilateral lower abdominal discomfort,

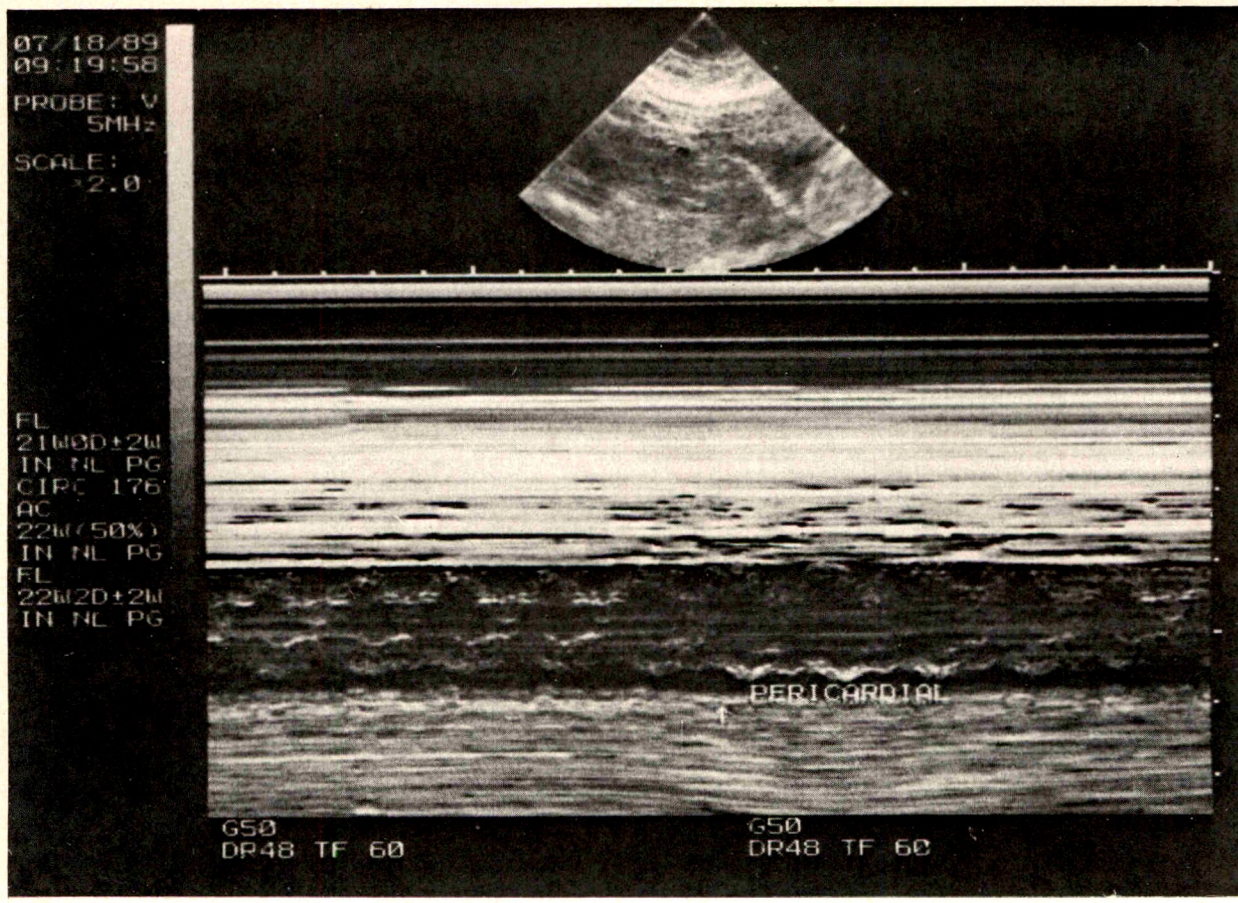

Fig. 1. M-mode echocardiogram of fetus in case 2. Pericardial effusion *(small arrow)* was detected below left atrium.

loose stools, and fever. Her symptoms were not associated with dysuria, vaginal discharge, or leakage of amniotic fluid. The physical examination revealed an uncomfortable, diaphoretic pregnant woman. Vital signs were normal except for fever of 38.8° C. Both urinalysis and culture results were negative. The uterus was diffusely tender to palpation. Real-time ultrasonography of the uterus demonstrated severe oligohydramnios and a viable fetus with right hydronephrosis and biometric criteria suggestive of growth retardation. Because the differential diagnosis included amnionitis, a transabdominal amniocentesis was performed with aspiration of 17 ml of clear amniotic fluid. Both Gram stain and bacterial culture of amniotic fluid were negative. However, viral culture of the amniotic fluid was positive within 72 hours. The identity of the viral isolate as cytomegalovirus was confirmed by a cytomegalovirus-specific monoclonal antibody. Serologic testing for specific maternal antibodies to cytomegalovirus revealed no IgM response (0.10 enzyme-linked immunosorbent assay units; negative), but a cytomegalovirus-specific IgG titer was positive at 0.50 enzyme-linked immunosorbent assay units (mid-positive).

Labor was induced at 38 weeks' gestation to facilitate treatment if required. The patient was delivered vaginally of a 2470 gm male with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. Physical examination revealed an active newborn without stigmata of congenital cytomegalovirus infection. An ultrasound examination confirmed the presence of unilateral right hydronephrosis. Although an ultrasonogram of the brain on day 1 revealed a normal ventricular system without calcifications, a second study done 1 week later showed a developing cystic formation in the caudate nucleus. The cerebrospinal fluid had an elevated cell count (2281 monocytes/mm^3) and elevated protein (100 mg/dl). Bacterial cultures were negative. A virology culture of the cerebrospinal fluid was not obtained. Nevertheless, these results are suggestive of continued postnatal viral disease in the central nervous system. Viral cultures of the infant's throat secretions and urine on day 2 of life both grew cytomegalovirus.

Case 2. The patient was a 25-year-old white woman (gravida 3, para 1) referred to the University of Iowa Fetal Diagnosis and Treatment Unit at 23 weeks, after routine ultrasonography demonstrated what was thought to be a left pleural effusion. The mother denied any recognizable illness during the gestation. When a level II ultrasonographic examination was con-

ducted, the effusion was noted to be pericardial rather than pleural (Fig. 1). An intermittent bradyarrhythmia also was documented. Amniotic fluid volume and fetal biometric parameters were within normal range.

Amniocentesis was performed to determine fetal karyotype and obtain viral cultures. Maternal serum was drawn on the same visit. It was positive for both cytomegalovirus-specific IgG (1.77 ELISA units; high positive) and cytomegalovirus-specific IgM (0.35 ELISA units; low positive). The amniotic fluid culture grew cytomegalovirus. Chromosomal analysis revealed a normal 46,XY karyotype. A third ultrasonographic examination 1 week after the second demonstrated complete resolution of the pericardial effusion. The fetus continued to grow appropriately for the duration of the gestation and weighed 3440 gm when delivered spontaneously at term. Physical examination of the newborn revealed no signs of congenital cytomegalovirus infection.

Comment

Cytomegalovirus, a member of the family *Herpesviridae*, is the most common cause of congenital infection.[2] The mechanism of cytomegalovirus transmission to the fetal tissues remains to be elucidated but is thought to occur hematogenously. Because the kidney is an organ that is commonly involved during cytomegalovirus infection, the infected fetus presumably excretes cytomegalovirus via fetal urine into the amniotic fluid. In addition to our two cases, there have been eight previous case reports of antenatally diagnosed cytomegalovirus infection after amniocentesis.[2] With this increasing number of case reports, we suggest that cytomegalovirus culture of amniotic fluid be considered in pregnant women in whom primary cytomegalovirus infection is suspected (e.g., in symptomatic pregnant adolescents, as in our first case). Similarly, cytomegalovirus cultures of amniotic fluid may be indicated when second-trimester ultrasonography reveals fetal problems compatible with acute viral infection, as in our second case.

Pelvimetry by magnetic resonance imaging in breech presentation

Aren J. van Loon, MD,[a] Albert Mantingh, MD, PhD,[a] Cornelis J. P. Thijn, MD, PhD,[b] and Eduard L. Mooyaart, MD, PhD[b]

Groningen, The Netherlands

Evaluation of the pelvis by pelvimetry plays an important role in selecting patients with term breech presentation for possible vaginal delivery. X-ray pelvimetry involves the disadvantage of fetal exposure to ionizing radiation. Computed tomography reduces the amount of radiation markedly, but there is still a risk. Ten patients with breech presentation at term underwent antepartum pelvimetry with magnetic resonance imaging, followed by postpartum magnetic resonance pelvimetry and x-ray pelvimetry. Measurements with magnetic resonance imaging are as reliable as those obtained with x-ray pelvimetry and the contrast of the magnetic resonance images is even better. The advantages of magnetic resonance pelvimetry are clear: no ionizing radiation and reliable pelvimetry results in cases of term breech presentation in which a normal pelvis is a prerequisite for safe vaginal delivery. (AM J OBSTET GYNECOL 1990;163:1256-60.)

Key words: Magnetic resonance imaging, breech presentation, pelvimetry

Controversy continues to exist regarding the value of pelvimetry.[1-3] It should be emphasized that a distinction must be made between pelvimetry in vertex presentation and in breech presentation. The value of pelvimetry in vertex presentation is doubtful; usually trial of labor can be allowed in all cases provided that high and midforceps deliveries are abandoned ("the fetal head is the best pelvimeter").

In breech presentation the value of pelvimetry is clear, provided that other parameters are considered in addition to the result of pelvimetry when deciding whether a term breech presentation can be delivered vaginally.[4-11] The disadvantage of x-ray pelvimetry is clear: ionizing radiation.[12] With computed tomography the radiation dose is reduced by approximately 65% but a certain radiation load still exists.[13, 14] Ultrasonographic pelvimetry is often unreliable and the pelvic configuration cannot be established properly. With magnetic resonance imaging (MRI) a new method for pelvimetry has become available. This technique makes imaging in multiple planes possible and combines the advantages of conventional or computed tomographic pelvimetry with the benefits of ultrasonographic techniques (no ionizing radiation).[15, 16] To evaluate the reliability of this relatively new method for pelvimetry, antepartum MRI was performed in 10 patients with breech presentation at term. This was followed by postpartum pelvimetry with MRI and conventional x-rays. The results of all three investigations were compared. To our knowledge this is the first report of magnetic resonance pelvimetry compared with conventional x-ray pelvimetry and antepartum pelvimetry compared with postpartum pelvimetry.

Material and methods

From April 1987 to May 1988 MRI pelvimetry was performed in 10 patients near or at term (36 to 41 weeks). The actual time was determined by the time of referral because of breech presentation and by the availability of the MRI equipment. Patients were informed about the study and its procedure by their own physicians, who were not involved in the study. It was explicitly explained that participation or refusal would not influence clinical management. Patients were informed that the results of the pelvimetry would have no influence on the decision about the mode of delivery. (Only postpartum conventional x-ray pelvimetry in selected cases is performed in The Netherlands.) Oral informed consent was obtained from all patients who agreed to participate. The study was approved by the Institutional Medical Ethical Committee. In the first week post partum (in two patients several weeks later) pelvimetry was repeated with MRI and conventional x-rays. The MRI pelvimetry was repeated to exclude

Pelvic distances and angles *a-b*, Obstetric conjugate (≥11.5 cm); *1*, pelvic inlet angle (≥115 or ≤150 degrees); *2*, pelvic aperture angle (≥80 or ≤120 degrees); *c-d*, interspinal distance (≥9.5 cm); *e-f*, intertuberal distance (≥10.5 cm). Values given are considered critical diameters and angles for allowing vaginal delivery of a term breech.

differences between the antepartum and postpartum situations. On the lateral or sagittal view the obstetric conjugate, the angles formed by the obstetric conjugate, the lumbar and sacral spine, respectively, were measured and we described the configuration of the pelvis. The purpose of measuring the pelvic inlet angle formed by the obstetric conjugate and the lumbar spine, and the pelvic aperture angle, formed by the obstetric conjugate and the sacral spine, is to obtain information about the axis and the configuration of the pelvic cylinder. Abnormal configuration might cause the breech to be caught on the symphysis, or cause rotation problems of the unmolded aftercoming fetal head.[17] On the anteroposterior or coronal view the interspinal and the intertuberal distances were measured. The minimal acceptable pelvimetry data for vaginal delivery of a term breech were derived from previous studies.[3, 17] The pelvic distances and angles with critical values are shown in Fig. 1.

The magnetic resonance images were obtained with a 1.5 tesla magnet system (Philips, Eindhoven, The Netherlands; Gyroscan). Sagittal (Fig. 2) and coronal (Fig. 3) slices 10 mm thick were made with a repetition time of 650 msec and an echo time of 20 msec. Data were acquired with a 256 × 180 matrix. The x-ray images were obtained in accordance with Guthman's method (one-shot lateral pelvimetry, patient in lateral position with hips and knees in slight flexion and a lead rod, with centimeter markings, between the legs; cen-

tration on femoral head), and a second radiograph was taken in anteroposterior direction. In every patient ultrasonographic examination was done to estimate the fetal body weight and the biparietal diameter and flexion of the fetal head and to determine the placenta localization. The duration of magnetic resonance pelvimetry was approximately 15 minutes; duration of x-ray pelvimetry was about 10 minutes.

Of the original group of 12 patients, two were excluded from further participation because of extreme claustrophobia during postpartum magnetic resonance pelvimetry. Statistical analysis of all the results was performed with the Wilcoxon rank-sum test for paired samples.

Results

The mean values (including SDs) of the obstetric conjugate, interspinal distance, intertuberal distance, pelvic inlet angle, and pelvic aperture angle and the levels of significance are shown in Table I. No differences in the general description of the configuration of the pelvis were observed. In Table II the data for all patients are shown. The antepartum magnetic resonance pelvimetry was used for the pelvimetry description. Only one of the 10 patients was delivered vaginally. Four cesarean sections were performed because of lack of progress during labor. Two of these patients had an abnormal pelvis; pelvimetry of patients no. 1 and no. 9 showed an abnormal configuration (Fig. 4) and a

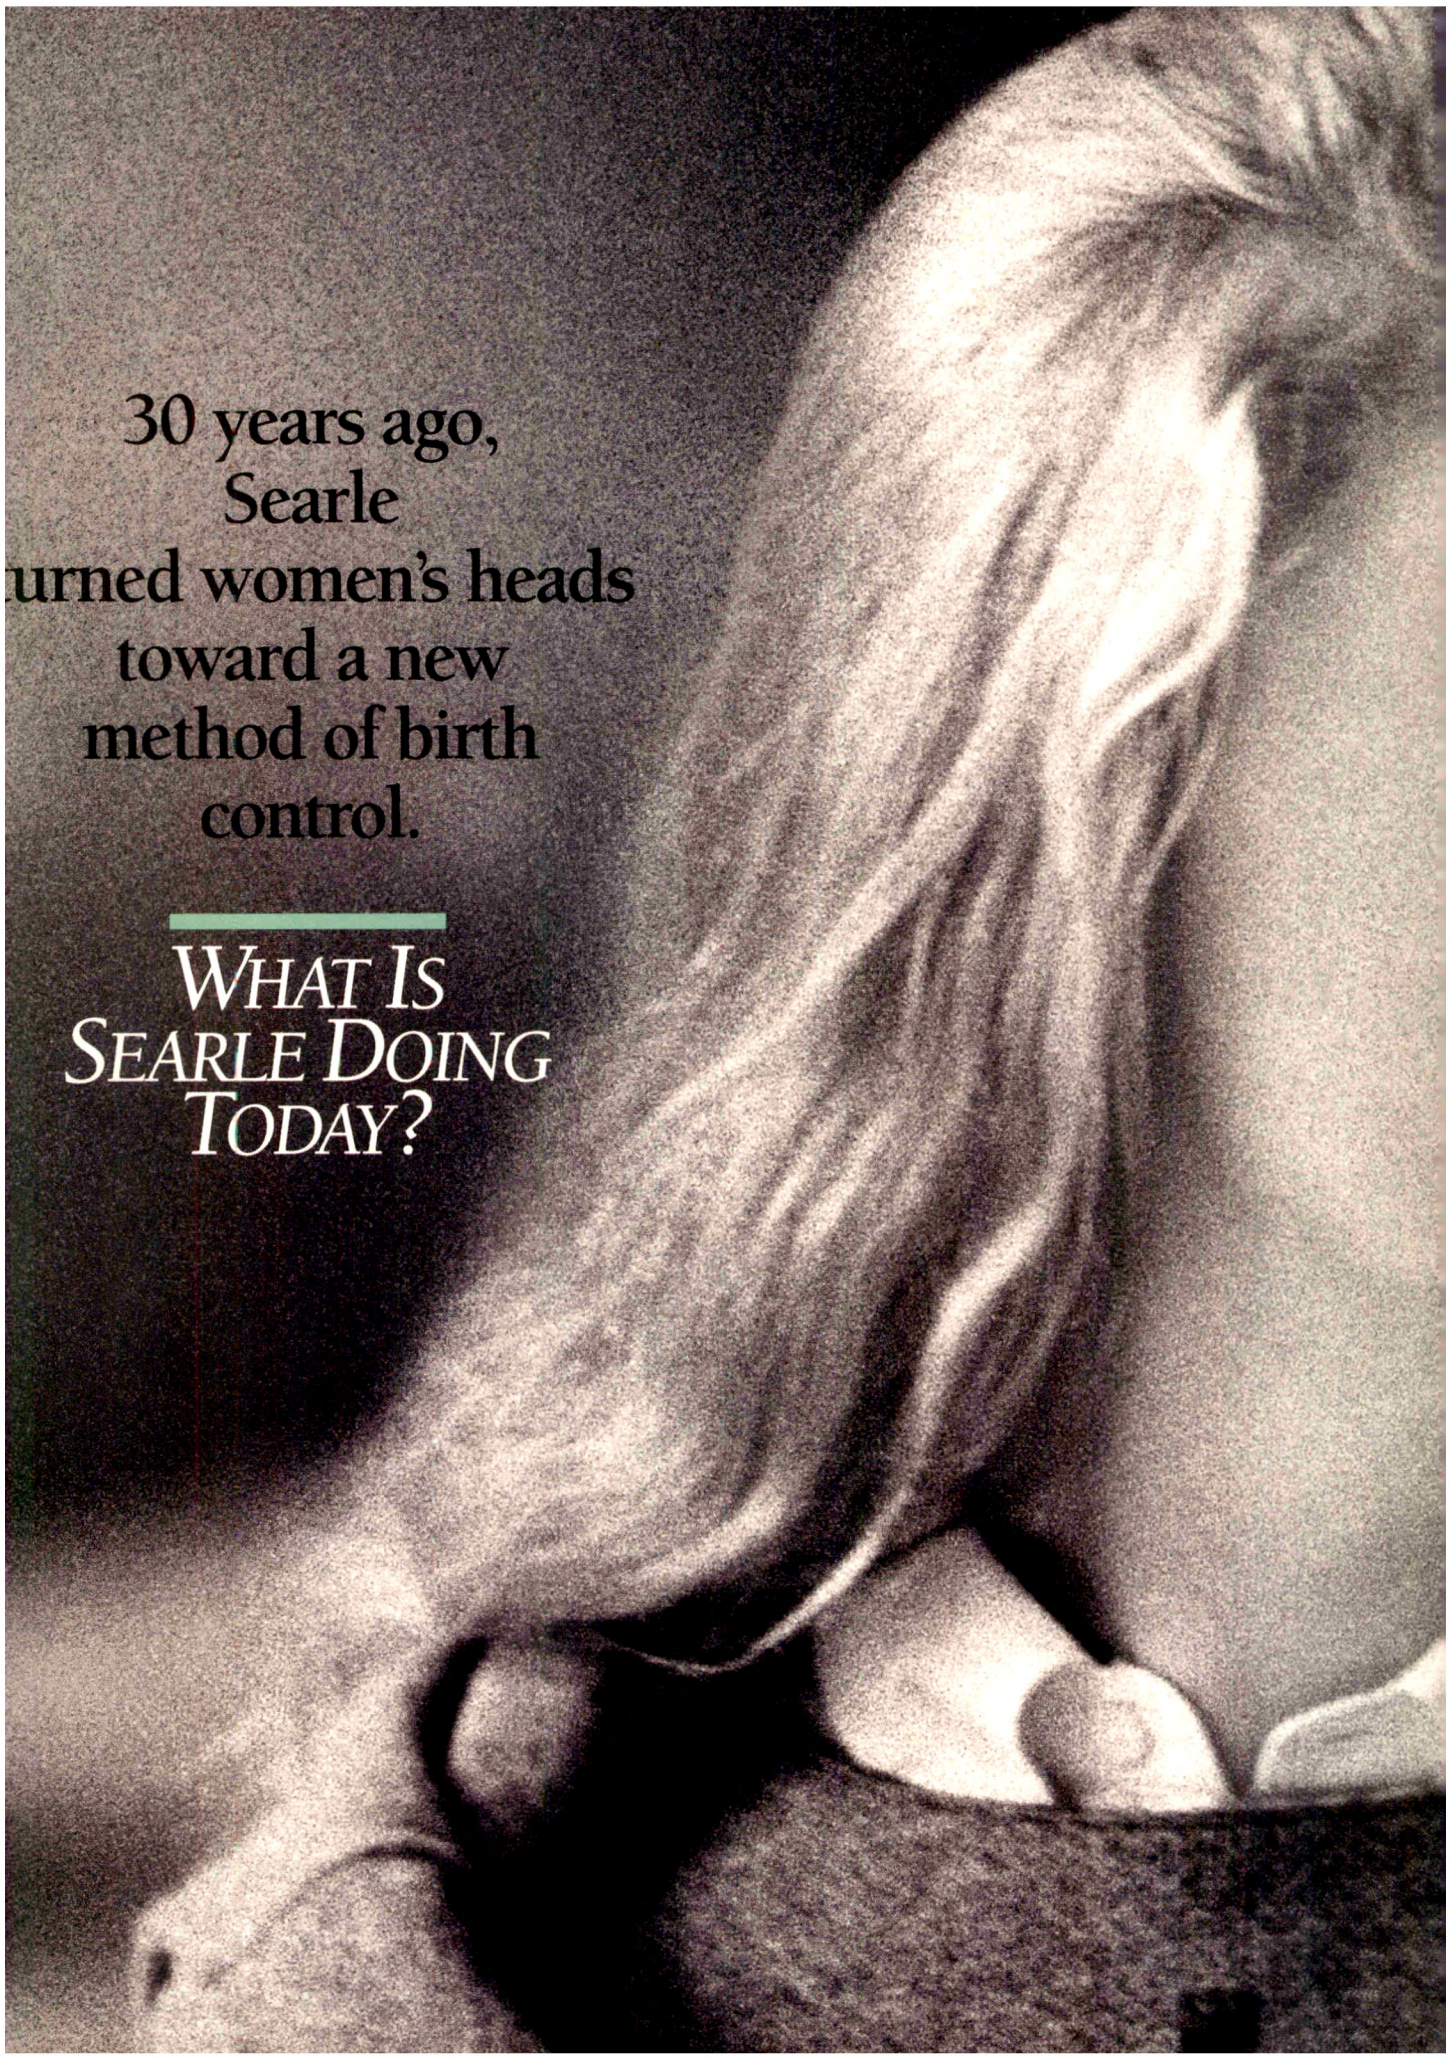
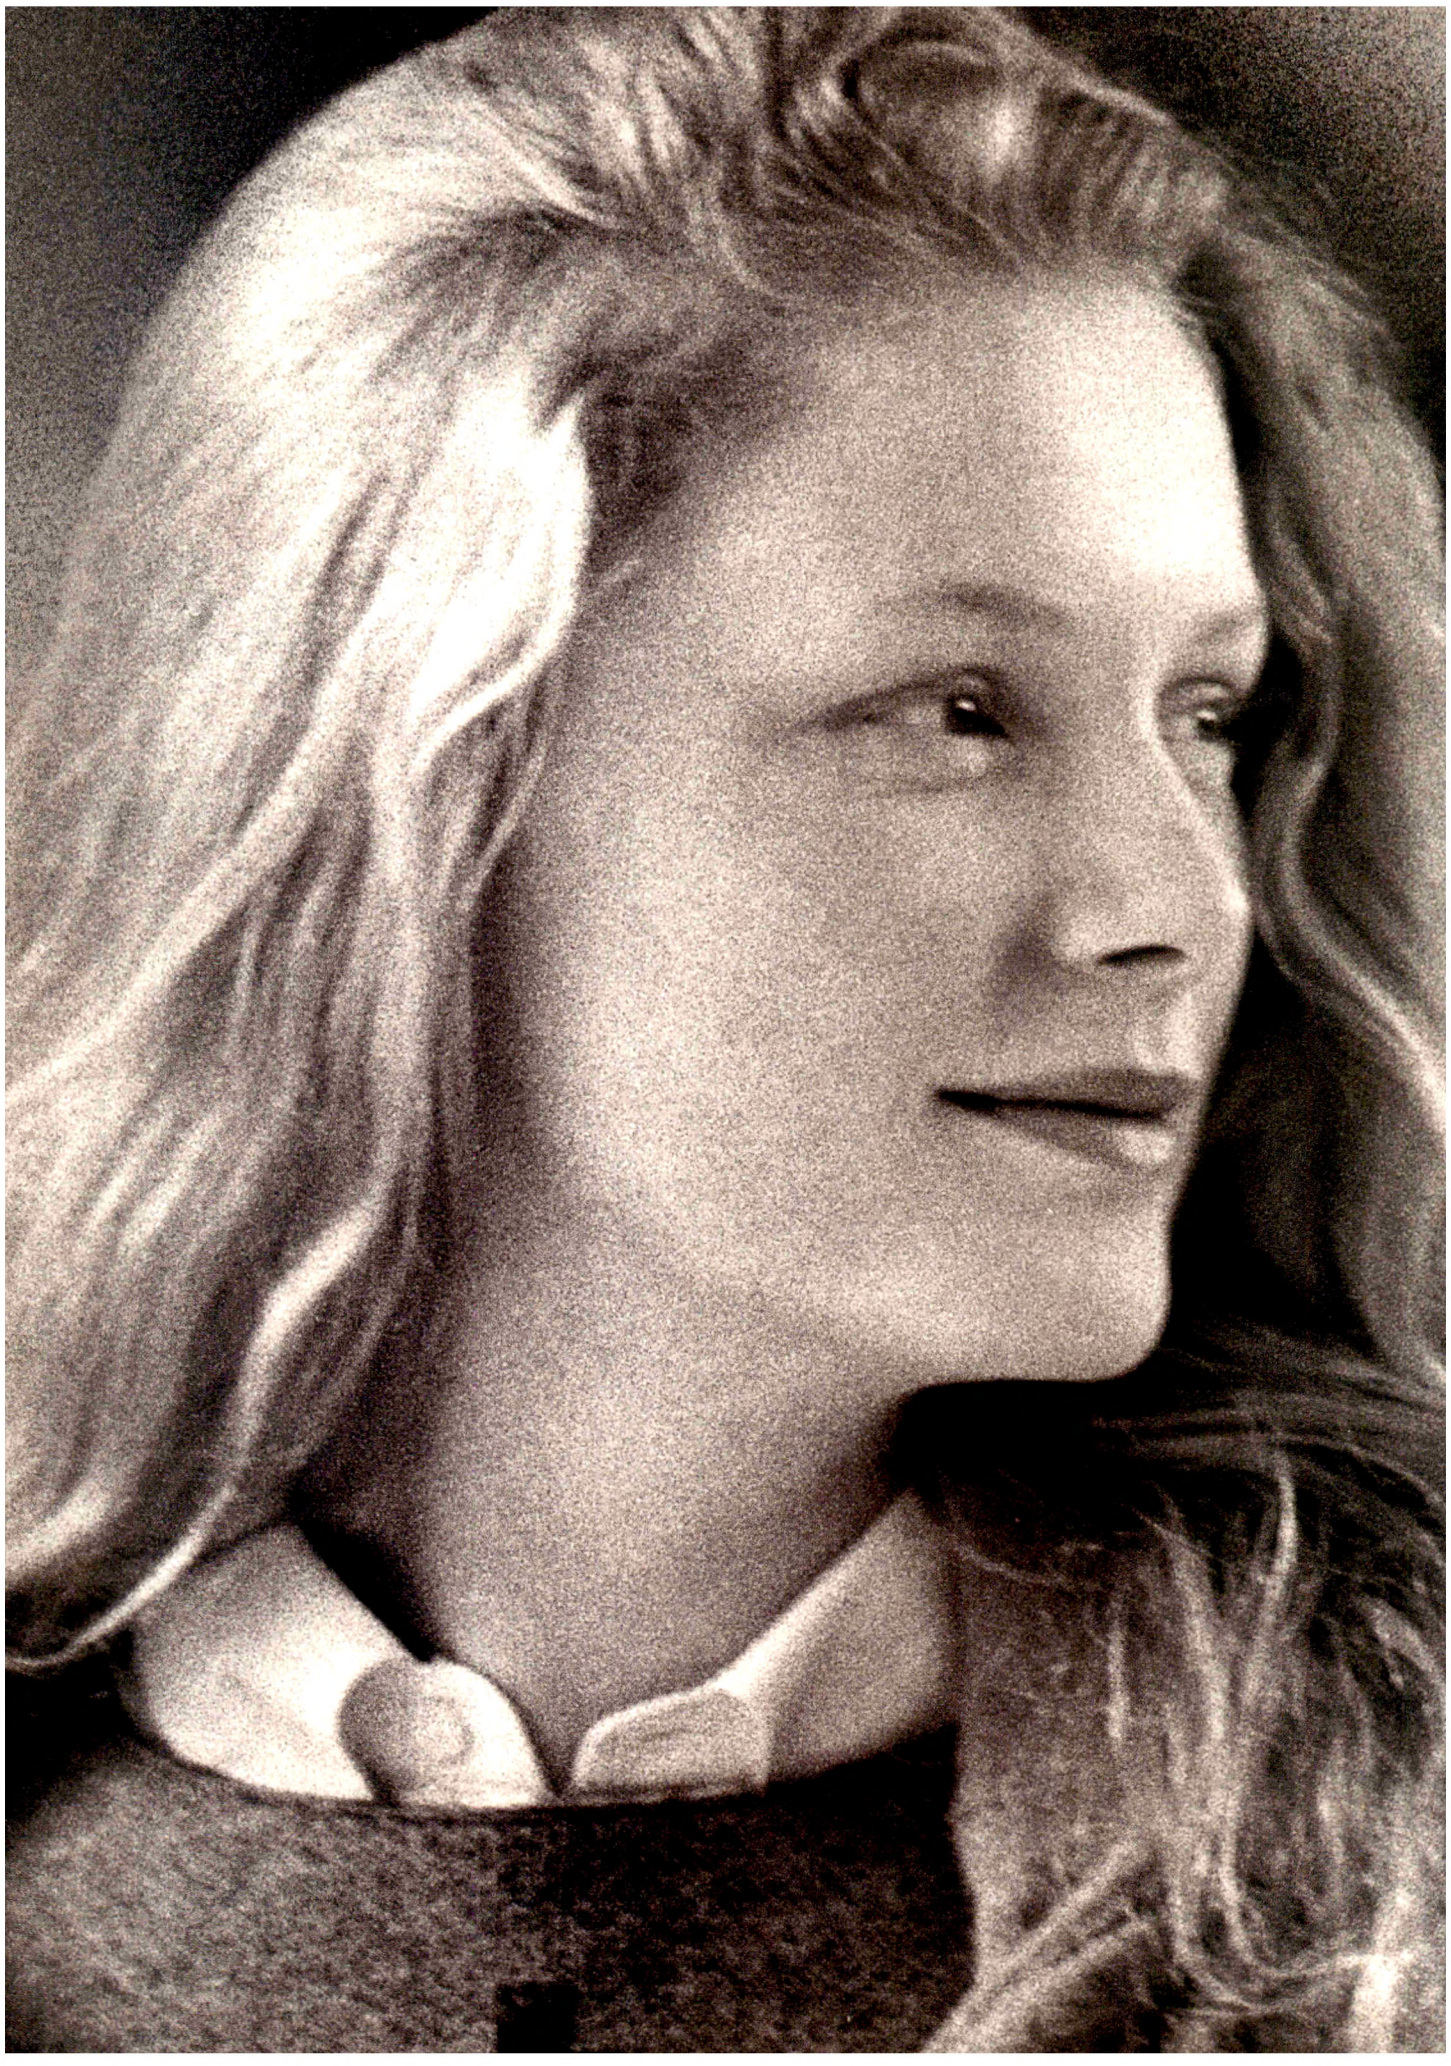
small interspinal distance (<9.5 cm). Of the five patients who had elective cesarean sections, patients no. 5 and no. 7 had completely normal pelvimetry and manual pelvic assessment results. Three patients (nos. 3, 6 and 8) appeared to have abnormal pelvic angles.

Comment

The obstetric conjugate appears to be longer during pregnancy than post partum; this difference is significant at the 5% level. However, the clinical relevance is questionable and the only conclusion that can be drawn is that the generally acccepted minimum x-ray values might be too cautious. Differences were found between the interspinal and intertuberal distances on the magnetic resonance pelvimetries, on the one hand, and the x-ray pelvimetries, on the other, but not between the two magnetic resonance pelvimetries. The interspinal distance on the x-ray pelvimetry was smaller and the intertuberal distance was larger than on the magnetic resonance pelvimetry. An explanation for the differences might be that x-ray pelvimetry in the anteroposterior view is not always reliable. In many cases this x-ray image was not very clear. However, the differences were so small that it was considered acceptable to apply x-ray image values that are acceptable for vaginal delivery to the magnetic resonance images. Mag-



netic resonance pelvimetry was particularly suitable for assessment of the pelvis because there were no differences between the general descriptions, and the contrast of the magnetic resonance images was superior. After review of the results per patient it appears that elective cesarean section was performed in two cases (No. 5 and No. 7) with a normal pelvis (on manual and pelvimetry assessment) because of a high presenting part. With the knowledge obtained from magnetic resonance pelvimetry, vaginal delivery would have been acceptable. In two patients (No. 1 and No. 9) the pelvis was normal on manual assessment, whereas pelvimetry showed abnormal values. In these two patients vaginal delivery was thought to be acceptable but the pelvimetry results favored an elective cesarean section. As in patients 4 and 10 it is clear that even if the manual assessment and pelvimetry are normal, cesarean section can be inevitable because of lack of progress during vaginal delivery. Patients 3, 6, and 8 showed that the manual assessment was confirmed by magnetic resonance pelvimetry. We therefore conclude that although magnetic resonance pelvimetry results alone should never be the only parameter for accepting or rejecting vaginal delivery in breech presentation, a normal pelvis is the most important factor. This study shows that precise pelvimetry is possible with MRI and that a good general impression can be obtained of an abnormal configuration, even if the distances are normal. A manual assessment is insufficient: the negative predictive value in our group was only 71.5%. If an obstetrician decides that a cesarean section is indicated in any breech presentation at term, all types of pelvimetry will be useless. However, if vaginal delivery is thought to be acceptable under certain conditions, we believe that pelvimetry should be included in the evaluation of these conditions. Magnetic resonance pelvimetry may prevent unnecessary cesarean sections, it may prevent a wrongly accepted vaginal delivery, and it certainly prevents the fetus from being exposed to ionizing radiation. The contraindications to the use of this scanning technique are limited: only patients with artificial, metal-containing heart valves, pacemakers, and vascular metal clips, etc., have a contraindication. Extreme claustrophobia might appear to be a relative contraindication. There are no known or foreseeable hazards or risks for mother or fetus associated with MRI.[18]



At present MRI is still relatively expensive compared with computed tomography and conventional x-ray pelvimetry (two and eight times, respectively) and is not yet available on a large scale. However, the costs of a MRI scan will soon be the same as a computed tomographic scan. With the arrival of new MRI systems, such as the Gyroscan T5, many hospitals will have an MRI system in the near future. These new systems are less expensive, easier to use, do not require special constructions, and might cause less claustrophobia because the design allows more space for the patient.

Our results indicate that magnetic resonance pelvimetry provides reliable information about the geometry of the pelvis without the use of ionizing radiation. The study shows that magnetic resonance pelvimetry is technically accurate and could now be used to assess the predictive value of this new diagnostic tool for a safe clinical management of breech presentation at term. A prospective study with a larger series of patients is required.

SEARLE DOING
TODAY?

MAKING A GREAT CASE FOR DEMULEN® 1/35

THE CASE FOR PRESCRIBING DEMULEN 1/35

- Low-dose formulation
- Minimal lipid impact
- Low incidence of some common androgenic side effects, such as acne, oily skin, and hirsutism
- Unique progestogen: ethynodiol diacetate
- No generic substitute available
- Covered by the Patient Promise® program

  If you prescribe Demulen 1/35, or any other Searle product, and do not achieve the desired therapeutic benefits, at any time, Searle will refund 100% of your patient's out-of-pocket cost for her most recent prescription for that product, *a full refund directly to your patient.*

DEMULEN® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Also available in the new Compack®
DEMULEN® 1/50 (ethynodiol diacetate 1 mg, ethinyl estradiol 50 mcg)

Please see adjoining page for a brief summary of prescribing information.

The physician should become familiar with the prescribing information (labeling) for this product, which discusses reported risks, such as thromboembolic disorders (including strokes and heart attacks), risk of estrogen dose, and hepatic lesions, as well as the need to monitor patients for early symptoms of any diseases or medical conditions, so use can be discontinued when appropriate. A brief summary of the prescribing information accompanies this advertisement.

DEMULEN® 1/35

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

BRIEF SUMMARY

Demulen® 1/35: Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients. **Demulen® 1/50:** Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients.

Indication and usage: For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk*: Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen.

Contraindications: Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products.

Warnings:

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. *Thromboembolic disorders and other vascular problems:* Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders:* In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction:* Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking is a major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers		10.2	2.6		62.0	15.9
≥15 cigarettes daily		13.0	5.1		78.7	31.3
<15 cigarettes daily		4.7	0.9		28.6	5.7
Nonsmokers		1.8	1.2		10.7	7.4
Smokers and nonsmokers		5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. Latter group also had more venous TE. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. Decreased HDL, which relates to increased myocardial ischemia, occurs with high progestational activity. Consider amount of both steroids in choosing OC. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases:* A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low.	Age:	<30	30-39	≥40
Heavy smokers (≥15/day)		C	B	A
Light smokers (<15/day)		D	C	B
Nonsmokers, no predispositions		D	C,D	C
Nonsmokers, with predispositions		C	C,B	B,A

Be alert to earliest manifestations of TE disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. RCGP reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. Varicose veins have little effect on development of deep vein thrombosis. **2.** *Ocular lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma:* Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. Estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased er cancer with combination or progestogen-only OCs. Studies show no increased breast cancer with OCs or estrogens. greater risk was noted in OC users with benign breast disease or long-term (2-4 years) use. One study found grea breast cancer with >4 years OC use prior to first full-term pregnancy. Risk of breast cancer with menopausal estro and further increased with duration of follow-up. OCs or estrogen were related to breast cancer in connection with factors and in various subgroups. Decrease in benign breast tumors in OC users is well known. Some studies increased risk of cervical dysplasia, CIN, erosion, and carcinoma in long-term users. Cervical microglandular hyper been reported. In summary, there is no consistent evidence from human studies of increased cancer risk with O surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consider nor causes and take diagnostic measures to rule out malignancy. Carefully monitor users with strong family history cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical **4.** *Hepatic adenomas, etc.* have been associated with OCs. In 1 study OC formulations with high "hormonal pote associated with higher risk, as was age over 30. Though benign, these lesions may rupture and cause fatal hemop in short- or long-term users. Two studies related risk to duration of use, being much greater after ≥4 years. Lon users have an estimated adenoma incidence of 3-4/year/100,000. Consider such lesions in users with abdom tenderness, mass, or shock. About 25% present with abdominal masses, up to half with acute hemoperitoneum. and lab studies may not be helpful; liver scans may show local defect. Hepatic arteriography or CAT may Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. Bile duct cancer may occur wit **5.** *Use in or immediately preceding pregnancy, birth defects, malignancy in offspring:* Estrogens or progestogens d pregnancy may seriously damage offspring. Females exposed in utero to DES and other nonsteroidal estrogens increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monitor such patients carefully. 90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. DE daughters have more unfavorable pregnancy outcomes. Males so exposed may develop urogenital and sperm defe estrogens may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, eg, VA vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects. There appears preferential expression by ma was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal pregnancy tests, or treatment for threatened abortion). Some exposures were very short, being only a few days. Card defects in children exposed to female hormones, including OCs, during early pregnancy occurred in 18.2/1,0 compared to 7.8 for those unexposed (P<.05). Female hormone exposure in utero was associated with testicular a cancer. More twinning was reported in conceptions shortly after OC discontinuance. Female sex hormones were threatened or habitual abortion, but there is considerable evidence estrogens are ineffective and no evidence pro are effective. Triploidy and possibly other polyploidy may be increased in abortuses from women becoming preg post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion is increased soon afte OCs. Increased chromosome aberrations have been reported. Safety of OCs in pregnancy has not been demonstr out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods a rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period an OCs. If pregnancy is confirmed, stop OC and apprise patient of potential fetal risks and discuss continuation of Users discontinuing for pregnancy should use alternative contraception for 3 months before attempting to conceiv this is not based on precise information. Do not use progestogen-only or progestogen-estrogen drugs as pregna **6.** *Gallbladder disease* risk, surgically confirmed, appeared after 2 years' use and doubled after 4-5 years in 1 appeared in 6-12 months' use in another. Bile duct cancer has been reported. **7.** *Carbohydrate and lipid metabolism:* glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Trig total phospholipids, and lipoproteins may increase. **8.** *Elevated blood pressure* (BP) occurs in some users in a few and degree may relate to progestogen dose. Hypertension prevalence in users is not higher in the first year, but with longer exposure; in the 5th year it is 2½–3 times the first year. Age is strongly correlated with hypertension Those with history of elevated BP (hypertension), preexisting renal disease, history of toxemia or elevated BP in p familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Even though elevated B in "normal" range, do not ignore implications. Follow closely, particularly those with other risk factors for card disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache:* Onset or exacerbation of m development of headache of a new pattern that is recurrent, persistent, or severe requires stopping OCs and evaluat **10.** *Bleeding irregularities:* Breakthrough bleeding (BTB), spotting, and amenorrhea are frequent reasons for discon BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent ble out pregnancy or malignancy. If pathology is excluded, time or change to another product may suffice. Change to estrogen OC only when necessary as this may increase thromboembolic risk. Those with history of oligomer secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinui with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolo occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors has been with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors with postpill amenorrhea when galactorrhea was present. **11.** *Ectopics:* In failures with combination OCs, the ratio to intrauterine pregnancies is no higher than in nonusers. **12.** *Breast feeding:* OCs may decrease quantity and quali A small fraction of OC steroids appears in milk. Effects if any on child are unknown. If feasible defer OCs until afte **13.** *Infertility* may occur after discontinuing OCs. While impairment diminishes with time, there is still an appreciable in nulliparas aged 25-29 after 30 months; difference is negligible after 48 months. In nullips aged 30-34 impairmer to 72 months and is more severe for 2-year users. In paras aged 25-34, difference is negligible after 30 months. **Pr** Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen, and p BP, Pap, and lab tests. Preexisting uterine leiomyomata may enlarge. Mental depression may occur; with positi observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monito in convulsive disorders, migraine, asthma, or cardiac, hepatic, or renal dysfunction. History of jaundice in pregnancy risk of recurrence on OCs; observe carefully and discontinue if it occurs. Cholestatic jaundice occurred afte troleandomycin use. OC/cyclosporine combination may be hepatotoxic. Steroids may be poorly metabolized in liver d and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; me anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise p of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests afte for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T^4); decreased T^3 uptake, una T^4, decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, tr phospholipid, reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolong on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response not established. OCs may mas climacteric. Cervical chlamydial and gonorrheal prevalence is increased; do not assume OC protects against chlam HIV seropositivity was associated with OC use. *Information for patients*. See patient labeling. *Drug interactions*. OC eff may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomycin, penicillin V, tetracycline, chlorar sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine, primidone, phenylbutazone, a tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants, anticonvulsants, tranquilizers antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, aceta **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thromb and thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrom adenomas and other hepatic lesions, with or without intra-abdominal bleeding, liver cancer, congenital abnormalities evidence of association between the following and OCs, though confirmatory studies have not been done: r thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The following are believed drug relate vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enl secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate toleranc candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or r premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, pa nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema mul nodosum, hemorrhagic eruption, herpes gestationis, hidradenitis suppurativa, hemolytic uremia, malignant hyp impaired renal function, acute renal failure, sometimes irreversible, itching, vaginitis, porphyria, PVCs, abnor pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus eryth rheumatoid arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant n endometrial, cervical, breast, and bile duct carcinoma. **Acute overdosage:** Serious ill effects have not been repo large acute doses of OCs in young children. Nausea and withdrawal bleeding might occur. **Important note: prescribing information should be consulted prior to use and is available on request.**

Intraamniotic infection in the very early phase of the second trimester

Israel Goldstein, MD, Etan Z. Zimmer, MD, David Merzbach, PhD, Bezaleal A. Peretz, MD, and Etan Paldi, MD

Haifa, Israel

A total of 157 consecutive patients were studied in an effort to examine prospectively the incidence of asymptomatic intraamniotic infection in the early phase of the second trimester. All patients were referred for amniotic fluid karyotyping. In addition, the amniotic fluids were examined for Gram stain and were directly cultured on blood agar and MacConkey agar as well as in thioglycollate broth. We found positive amniotic fluid cultures in eight cases (5.09%); however, results of Gram stain examinations were negative in all amniotic fluid samples. The data indicate that there is no correlation between white blood cells in the amniotic fluid and positive amniotic fluid culture results. Only one pregnancy with positive amniotic fluid culture resulted in a septic abortion. Therefore we can suggest that intraamniotic infection can exist early in pregnancy, even with intact membranes, and in most cases without any clinical symptoms. (AM J OBSTET GYNECOL 1990;163:1261-3.)

Key words: Intraamniotic infection, microbiology, late abortion, amniocentesis, second-trimester infection

The notion that amniotic fluid remains sterile as long as the membranes are intact is no longer acceptable.[1-10] Recently many investigators have noted the presence of asymptomatic intraamniotic infection particularly associated with preterm labor in the second half of gestation.[2, 3] Bobitt and Ledger[4] were the first to report positive bacteriologic analysis of amniotic fluids obtained by amniocenteses from the amniotic cavity in women with intact membranes. The authors postulated the presence of unrecognized amnionitis, that is, positive amniotic fluid culture in an afebrile mother. Intraamniotic infection has been recognized as a major etiologic factor in preterm delivery.[4] The prevalence of positive amniotic fluid cultures has varied from 0% to 25.8%.[1-10] So far there has been no report of which we are aware on the incidence of asymptomatic intraamniotic infection in the early phase of the second trimester.

The study reported herein was conducted with a population of women with intact membranes; the women underwent amniocenteses for cytologic purposes at 15 to 19 weeks' gestation. The objectives of the study were: (1) to determine the microbiology of the amniotic fluid; (2) to establish the incidence of intraamniotic infection in this particular patient population; and (3) to ascertain pregnancy outcome.

From the Department of Obstetrics and Gynecology "B" and the Department of Microbiology, Rambam Medical Center, Technion Institute of Technology.
Presented at the Tenth Annual Meeting of the Society of Perinatal Obstetricians, Houston, Texas, January 23-27, 1990.
Received for publication February 23, 1990; revised June 14, 1990; accepted June 18, 1990.

Patients and methods

Patient population. A prospective study of the incidence of asymptomatic intraamniotic infection was conducted in a population of normal pregnant women referred for amniocentesis. Amniotic fluid was obtained by transabdominal amniocentesis from 157 patients with singleton pregnancies referred for karyotyping; gestational ages ranged from 15 to 19 weeks. The procedure was done in all cases under sonographic guidance by the same physician (I. G.). The indications for amniocentesis within the study population were: maternal age, 109 patients; low level of maternal serum α-fetoprotein, eight patients; high level of maternal serum α-fetoprotein, six patients; previous affected child, 18 patients; anxiety, eight patients; and miscellaneous, eight patients. The success rate for the amniocenteses was 100%, and in each patient no more than one puncture was necessary. Indications to perform amniocentesis were high level of maternal serum α-fetoprotein, low level of maternal serum α-fetoprotein, maternal age, previous affected child, and maternal anxiety.

Amniotic fluid processing for microscopic examination. Preparations for amniotic fluid puncture included mechanical scrubbing of patient's abdomen with 10% povidone-iodine and 70% ethyl alcohol for at least 4 minutes. Amniotic fluid was obtained under highly

aseptic conditions in standard test tubes for direct Gram stain, direct cultures, white blood cell count, and karyotyping. The specimens were delivered in sterile tubes to the microbiology laboratory within 5 minutes and processed immediately; white blood cells were examined in the hematology laboratory. The tubes were without anaerobic environment. To facilitate semiquantitative evaluation, a loopful of the specimen was smeared onto a solid medium. Approximately 0.5 ml of amniotic fluid was added to thioglycollate broth (Difco, Detroit) for enrichment and anaerobic growth. Gram stain examination was performed with standard reagents (gentian violet, Lugol solution, alcohol-acetone solution, and fuchsin, Sigma, St. Louis). The direct cultures were smeared onto a blood agar base and MacConkey agar.

All media were incubated in an atmosphere containing 5% carbon dioxide at 35° C ± 2° C for 24 to 48 hours. The specimens were examined by trained microbiologists after 24 and 48 hours. Pure cultures at primary isolation were used for identification of the microorganisms. In case of mixed flora, these were again inoculated to isolate pure cultures. Identification of the organisms was made with accepted microbiologic methods.[12]

We used the following semiquantitative definitions for the presence of microorganisms in the amniotic fluid: scant growth, <10 colonies per plate; intermediate growth, 10 to 20 colonies per plate; abundant growth, 20 to 40 colonies per plate; and overabundant growth; >40 colonies per plate. The presence and absence of white blood cells were also noted.

Statistical analysis was made with 95% confidence interval for the frequency of positive cultures.

Results

Between November 1988 and October 1989, 157 healthy pregnant women underwent routine amniocentesis. The indications for amniocentesis within the study population were: maternal age, 109 patients; low maternal serum α-fetoprotein level, eight patients; high maternal serum α-fetoprotein level, six patients; previous affected child, 15 patients; cystic hygroma, two patients; anxiety, eight patients; miscellaneous, eight patients. Two of the pregnancies with negative amniotic fluid cultures resulted in late abortions. Eight patients (5.09%) had positive amniotic fluid cultures (95% confidence interval 1.7% to 8.5%).

One patient with a positive culture of *Escherichia coli*, underwent a septic abortion 2 weeks after amniocentesis. Cultures obtained from the intrauterine cavity and placenta during the process of abortion also tested positive for *E. coli*.

Microbiologic examinations provided the following results: five cases of scant growth, one case of intermediate growth, one case of abundant growth, and one case of overabundant growth (see Table I).

Comment

Although development of overt chorioamnionitis in women with intact membranes is rare, recent studies have shown a high incidence of positive amniotic fluid cultures in preterm labor with intact membranes.[1-3] The majority of the patients have not had clinical signs of

chorioamnionitis. Romero et al.[3] reported a 9.1% prevalence rate of positive amniotic fluid cultures in women with preterm labor and intact membranes. Previous studies with the use of amniocentesis to determine the microbiologic status of the amniotic cavity in patients with preterm labor and intact membranes have documented a mean positive culture rate of 13.6% (46/339), with a range from 0% to 25.8%.[7]

Although most patients in these studies were not responsive to therapy with tocolytic agents and were delivered of infants prematurely, in some cases labor was delayed for a significant interval of time. It is of interesting that there were no clinical signs of sepsis in the majority of the delivered infants.

Prevedourakis et al.[11] examined the amniotic fluid of 39 women with intact membranes and no sign of preterm labor at 30 to 39 weeks' gestation. In one case (2.56%) intraamniotic infection was detected; the organism was *Proteus*. The patient was delivered of an infant at term, and no pathologic signs were noted either in the mother or in the newborn infant during the postpartum period.

In the present study we did not examine the amniotic fluid for mycoplasma species. We found a 5.09% incidence of aerobic infection (95% confidence interval, 1.7% to 8.5%); no anaerobic bacteria were found.

In the most interesting case in our study the patient had amniotic fluid with a scant growth of *E. coli*. Despite the relatively small growth the fetus was aborted. The same bacteria were found later in cultures taken from the uterine cavity and the placenta.

Microorganisms in the amniotic fluid indicate the presence of either infection in the lower genital tract or invasion through maternal circulation. However, we do not know the origin of the microorganisms found in the amniotic fluid and we do not have an explanation for the relatively good outcome of the patients with positive amniotic fluid cultures.

The results of the study were unexpected, particularly in view of the fact that the patient population was asymptomatic and low risk. In each instance the amniocentesis procedure was performed by the same obstetrician under strict aseptic conditions. Furthermore, the microorganisms present in the positive amniotic fluid cultures are not found under usual circumstances on the abdominal wall. Therefore the possibility of external contamination appears to be negligible.

A possible explanation for the inability to detect the presence of microorganisms on culture media may be provided by the fact that antibiotics are routinely added to amniotic fluid culture media in the cytogenetic laboratory.

Further investigation should be undertaken. Whereas we can assume that antibiotic treatment may eradicate infection in the amniotic cavity, the clinician's dilemma remains—to treat or not to treat the patient with positive amniotic fluid culture.

In conclusion, we can suggest that intraamniotic infection can exist early in a pregnancy with intact membranes and in most cases without any clinical symptoms. We recommend bacteriologic evaluation of each amniocentesis; moreover, in cases with positive amniotic fluid cultures, antibiotic treatment might be indicated.

We gratefully acknowledge the assistance of Mrs. Judy Golub; without her cooperation this manuscript could not have been carried out.

Placental histology in fetuses between 18 and 23 weeks' gestation with abnormal karyotype

R. S. Kuhlmann, MD, PhD, A. L. Werner, MD, J. Abramowicz, MD, S. L. Warsof, MD, J. Arrington RDMS, and D. L. Levy, MD

Norfolk, Virginia

Placentas from karyotypically abnormal fetuses (18 to 23 weeks' gestation) were analyzed prospectively at the light microscopic level. Group I consisted of 14 control placentas. Group II consisted of 14 placentas from fetuses with an abnormal karyotype. Secondary and tertiary stem villi counts, small muscular artery counts, and total vessel counts were determined per 100× field. There were no differences in secondary and tertiary stem villi counts between groups. A significant decrease in small muscular artery counts ($p < 0.01$) and total vessel counts ($p < 0.01$) was noted in group II. Placental and fetal weights were comparable between groups. This undervascularization may represent placental immaturity as a result of arrested or delayed angiopoiesis. It appears that this abnormality is established before the third trimester and may be enhanced by late vascular obliteration as reported by others. These data substantiate the concept that the structure and function of the placenta is determined to a great degree by fetal karyotype and may help explain the morbidity and mortality seen in these fetuses. (Am J Obstet Gynecol 1990;163:1264-70.)

Key words: Placental undervascularization, abnormal karyotype

Fetuses with chromosomal abnormalities, with or without an associated structural defect, are often growth retarded and have an increased rate of intrauterine death.[1, 2] The cause of this increase in morbidity and mortality is not clear. It is believed that the growth disturbance is genetically determined in part by the fetus.[1, 3] Recent studies have quantitatively demonstrated a significant correlation between placental undervascularization and abnormal Doppler velocimetry in the trisomic[2] and growth-retarded but karyotypically normal fetus[4, 5] in the third trimester. Abnormal Doppler velocimetry has also been documented in fetuses with major structural anomalies, but placental correlation is lacking in these studies.[6, 7] Our pilot study revealed many of the karyotypically abnormal fetuses to have abnormal Doppler velocimetry between 18 and 23 weeks' gestation. We are not aware of any authors who have addressed placental histopathology at this gestational age in the karyotypically abnormal fetus.

The purpose of this study was to quantitatively evaluate the microvascular anatomy of the placenta to determine whether placenta undervascularization reported in the third trimester is present between 18 to 23 weeks' gestation in the karyotypically abnormal fetus. The presence of this abnormality may be responsible for abnormal blood flow in the umbilical artery during this period of gestation.

Material and methods

Placentas were analyzed prospectively from two groups of fetuses from pregnancies terminated at 18 to 23 weeks' gestation. Group I consisted of 14 control placentas obtained from patients first seen at our tertiary care center in premature labor or with advanced cervical dilatation as a result of cervical incompetence. Group II consisted of 14 placentas from fetuses that were karyotypically abnormal with or without a structural defect. Placentas associated with abruptio placentae, clinical or pathologic evidence of chorioamnionitis, umbilical cords with one or two vessels, placenta previa, multiple gestations, hypertension, diabetes, and stillbirths were excluded from the study. Retained placentas were discarded unless 90% of the placenta was obtained intact by manual extraction. All pregnancies in

groups I and II had an ultrasonographic confirmation of gestational age. Placentas were weighed wet if intact and two or more tissue blocks were obtained 2 cm from the cord insertion and 2 cm from the placental edge after macroscopic evaluation by serial sectioning of the placenta at 1 cm intervals. Villous tissue that appeared unusual was avoided. Tissue blocks were fixed in 10% formalin, then embedded in paraffin. Sections (4 μm) were then stained with hematoxylin and eosin and trichrome. Slides stained with hematoxylin and eosin were used for initial evaluation and trichrome slides were used for counts because collagen and smooth muscle were better defined. Trichrome-stained slides were analyzed at magnifications of ×40 and then magnifications of ×100. Areas of infarct, fibrin deposits, and primary stem villi with anchoring stem villi were avoided. Midzone areas were analyzed and total vessel counts, small muscular artery counts, and secondary and tertiary stem villi counts[8] were established. Small muscular arteries (diameter up to 90 μm) and arterioles defined as vessels approximately capillary size (20 μm) with walls consisting of two layers of smooth muscle were counted per 100× field. Capillaries were also counted when secondary and tertiary stem villi counts were performed. Counts were reported per 100× field.

At least five fields per slide at a magnification of ×100 were counted by an anatomist-obstetrician (R. S. K.) and a pathologist (A. L. W.) who were not aware of gestational age and fetal status. Counting was repeated by each person on two occasions separated by at least a 1- to 2-week interval.

Doppler analysis. Ultrasound-guided continuous-wave Doppler analysis (Multigon 500A, Multigon Industries, Inc., Mt. Vernon, N.Y.) was performed on the umbilical artery in group II approximately 12 to 24 hours before pregnancy termination with prostaglandin vaginal suppositories. Absent end-diastolic flow or a resistance index ≥0.79 was considered abnormal on the basis of normograms used in our laboratory. Doppler analysis was not performed in group I because of advanced preterm labor.

Statistical analysis. The paired Student *t* test was used to evaluate the reproducibility of counting[4] and to establish possible intra- and interobserver differences. Fetal and placental weights were analyzed by a Student *t* test for independent samples. All counts in groups I and II were evaluated for a parametric or nonparametric distribution. Analysis of raw data revealed a nonparametric distribution and Mann-Whitney *U* analysis was used to determine whether differences existed between groups. In addition, modal counts were determined and analyzed by the Wilcoxon test as described in a previous study involving placental analysis in the third trimester.[4]

Results

Characteristics of groups I and II are depicted in Table I. Group II is further categorized with respect to karyotype and associated structural anomalies in Table II. Placental and fetal weights were comparable between groups I and II (Table III). Secondary and tertiary stem villi counts did not differ significantly between groups ($p = 0.19$). A significant decrease in small muscular artery counts ($p < 0.01$) and total vessel

counts ($p < 0.01$) was observed in group II as compared with group I (Table IV). No significant intraobserver differences existed between groups when counting was performed by both authors, (R. S. K.) and (A. L. W.), on two occasions separated by 1 to 2 weeks, demonstrating reproducibility of counting by each author. When interobserver comparisons were made, one author (R. S. K.) counted significantly more secondary

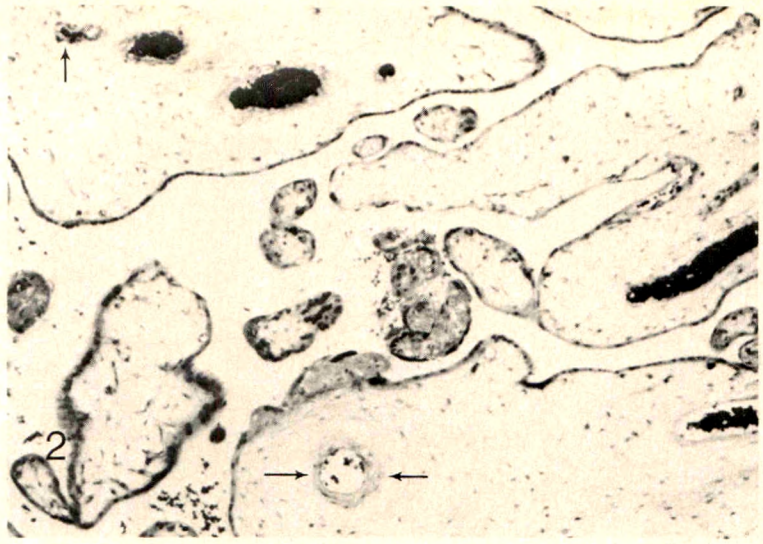

Fig. 2. Well-vascularized villi of control fetus at 22 weeks' gestation. *Double arrows* represent a muscular artery. *Single arrow* represents smaller muscular vessel and adjacent larger muscular vessel consisting of a smooth muscle bilayer. (Original magnification ×60.)

and tertiary stem villi ($p = 0.047$) in both groups as compared with the other author (A. L. W.). There were no significant differences when small muscular artery counts and total vessel counts were compared. Because of the lack of intraobserver variation and minimal interobserver variation and the same final findings of each author in groups I and II, data from R. S. K. only was used in this study. Modal counts were plotted in Fig. 1. Modal secondary and tertiary stem villi counts did not differ significantly (Wilcoxon test, $p = 0.06$). A significant decrease in modal small muscular artery counts ($p < 0.05$) and modal total vessel counts ($p < 0.05$) did exist in group II as compared with group I when analyzed by the Wilcoxon test. Six of the 14 fetuses (43%) in group II were found to have abnormal Doppler velocimetry. Photomicrographs of representative fields are depicted in Fig. 2 to 7.

Comment

It has been postulated that the placenta is the fetal organ and its structure and function are determined to a variable degree by fetal karyotype in human beings[2]

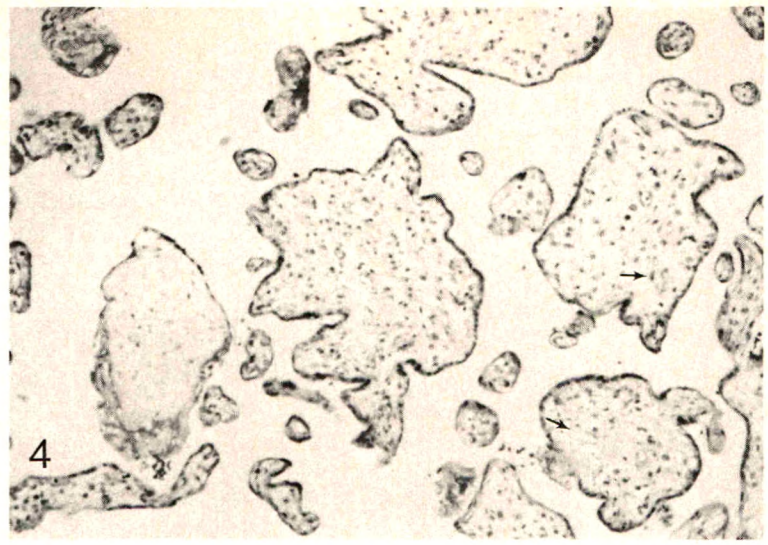

Fig. 4. Undervascularized villi of fetus with trisomy 18 at 22 weeks' gestation compared with Fig. 2. *Arrows* depict small vessels lacking walls composed of smooth muscle bilayer. (Original magnification ×60.)

and certain animal models.[9] Abnormal growth seen in fetuses with aberrant karyotypes is believed to be determined in part by the genotype of the fetus.[1, 3] Structural abnormalities of the placenta may also contribute to abnormal fetal growth.[2, 4, 5] A significant decrease in placental small muscular arteries and the small muscular artery to villus ratio has been demonstrated in the fetus with autosomal trisomy and in the normal but growth-retarded fetus during the third trimester.[2, 4, 5]

In this study fetal weights were comparable between groups despite a trend toward decreased weight in group II. Whereas there were no significant differences among the groups regarding secondary and tertiary stem villi counts, the total vessel counts and small muscular artery counts were significantly less in group II. Modal secondary and tertiary stem villi counts did not differ significantly (Wilcoxon test, $p = 0.06$). This result may be influenced by the limited number of cases available. A further evaluation of a larger number of

Fig. 6. Villi of fetus with 45,X and cystic hygroma at 21½ weeks' gestation. Note undervascularization and increased villous edema compared with Fig. 2. *Arrow* depicts small blood vessel without smooth muscle bilayer. (Original magnification ×60.)

cases may demonstrate a significant difference. Previous authors[2, 4, 5] have also noted obliteration of vessels in addition to the actual decrease in numbers of small muscular arteries. Obliterated vessels were rarely seen in placentas of groups I and II. Many placentas in group II had few or no small muscular arteries present as previously noted in the third trimester.[2] Villous edema was noted in both groups. Qualitatively this edema appeared greater in placentas associated with trisomy and 45,X and particularly those associated with a cystic hygroma. This may represent immaturity and appears to decrease with advancing gestational age. The significance of the selective increase in edema seen in these specific cases is not clear.

Recent studies[2, 4, 5] have demonstrated that as the number of small muscular arteries decreases, placental vascular resistance increases with subsequent decreases in end-diastolic blood flow within the umbilical artery. This has also been reported in the karyotypically abnormal fetus in the third trimester.[2]

In our pilot study, many fetuses with congenital anomalies had abnormal Doppler velocity waveforms between 18 to 23 weeks' gestation. In this study 6/14 (43%) fetuses exhibited abnormal Doppler velocimetry. Doppler studies were not performed on fetuses in group I, therefore only inferences can be made. Although speculative, the undervascularization seen in this study may explain our previous and current Doppler findings. This undervascularization seen in group II may represent placental immaturity as a result of arrested or delayed angiopoiesis. It appears that this abnormal vascularization is established before and continues into the late phase of the third trimester. In addition, the abnormality is probably enhanced by arterial obliteration as demonstrated by the work of others.[2]

To our knowledge, these are the first data comparing these two homogenous, yet different, groups of fetuses between 18 to 23 weeks' gestation. These results, added to the work of others performed in the late phase of the third trimester,[2] further our understanding concerning the morbidity and potential mortality seen in the karyotypically abnormal fetus. Last, these findings further substantiate the concept that the placenta is a fetal organ and that its structure and function are determined to a significant degree by fetal karyotype.

Carbon dioxide laser energy disperses human papillomavirus deoxyribonucleic acid onto treatment fields

Alex Ferenczy, MD,[a] Christine Bergeron, MD, PhD,[b] and Ralph M. Richart, MD[b]
Montreal, Quebec, Canada, and New York, New York

The possibility of dispersing viral deoxyribonucleic acid during carbon dioxide laser treatment of human papillomavirus–containing genital infections has been investigated with a commercially available dot blot hybridization technique. The viral ribonucleic acid probes were specific for groups of human papillomavirus types 6/11, 16/18, and 31/33/35. Laser energy was delivered by continuous-wave mode and the plume of smoke was evacuated by a vacuum suction system. Samples were taken with Dacron swabs from lesional tissues of 43 patients as well as from the treated areas and from the 5 cm surrounding normal skin before and after laser vaporization. Human papillomavirus deoxyribonucleic acid was identified in swabs from 34 of 43 (79%) lesional tissues and 7 of 43 (16%) treatment fields. Although a trend for higher human papillomavirus deoxyribonucleic acid positivity in laser margins after therapy (7/43, 16%) than before (4/43, 9%) was observed, the rates were not statistically significant. It is concluded that carbon dioxide laser energy disperses human papillomavirus deoxyribonucleic acid onto treatment fields and the adjacent normal epithelium. Viral contamination of treated areas may be reduced by positioning the fume evacuator within 1 cm of the field of laser vaporization and cleaning the treated areas and surrounding tissue after therapy. (AM J OBSTET GYNECOL 1990;163:1271-4.)

Key words: Carbon dioxide laser, smoke, human papillomavirus DNA, hybridization

Among the many treatment modalities available for human papillomavirus (HPV)–containing genital lesions, carbon dioxide laser therapy became one of the most attractive techniques employed in current gynecologic practice.[1] Carbon dioxide laser energy is largely absorbed by intracellular water that is instantaneously turned to steam resulting in the vaporization of lased cells. However, intracellular proteins and nuclear deoxyribonucleic acid (DNA) are water-free and thus are carbonized rather than vaporized. The resulting plume of smoke contains charred and partially or totally thermocoagulated cellular debris.[2] The plume is evacuated from the treatment field by suction. However, depending on the evacuation system used and the mode of its application during laser vaporization procedures, variable amounts of plume content may be dispersed onto treatment fields. Previous analyses failed to indicate viability of the carbonized particulates including those derived from normal and malignant cells as well as those from verruca and bacteria.[2-4] Most recently, however, in vitro bioassays found infectious bovine papillomaviruses in the smoke from bovine warts treated either with the carbon dioxide laser or electrocautery.[5] Concern has been raised that carbon dioxide laser vaporization of genital warts may also be associated with HPV DNA contamination of both the patient and the operating personnel. HPV DNA was found by experiments of hybridization in the plume of smoke generated by the carbon dioxide laser energy that was used to vaporize genital HPV infections in both humans[6] and animals.[7]

The purpose of this study was to determine, with the aid of a dot blot hybridization technique, whether lasing genital HPV infections in the human results in viral contamination of treatment fields.

Material and methods

Forty-three patients, 38 women and 5 men, aged 18 to 56 (mean, 30) in whom the histologic study was consistent with HPV infections of the lower genital tract have been treated in the Laser Surgery Unit of the Reddy Memorial Hospital, Montreal, with a Merrimack 840 carbon dioxide laser (Sigmacon, Toronto). The lesional tissues were ordinary condyloma acuminatum in 26 patients and low-grade (flat condyloma/cervical intraepithelial neoplasia grade 1) and high-grade (cervical intraepithelial neoplasia grades 2 and 3) intraepithelial lesions in the remaining 17 patients. The le-

sional areas treated ranged from 2 to 18 cm^2 (mean, 7 cm^2). The margins of lesional tissues were defined by the use of 5% acetic acid solution and colposcopy. Laser vaporization was done in four different treatment sessions each including 10 or 11 patients. Thirty patients were treated while under general anesthesia and the remaining 13 patients had local anesthesia. Laser energy was delivered with continuous-pulse mode; power outputs ranged between 20 and 50 W and spot sizes from 2 to 4 mm with power densities ranging between 500 and 1250 W/cm^2. Laser vaporization was generally extended between 5 and 10 mm beyond the margins of lesional tissue treated. Depth of penetration ranged from 5 mm (in the cervix) and 2 mm (hairy skin of the vulva) to 1 mm (vagina, nonhairy skin of vulva, and perianal skin) as measured by a laser ruler from the normal, adjacent surface epithelium. After each procedure the crater and surrounding epithelium were wiped with 5% saline solution. The operating room contained a wall-mounted exhaust system for evacuation of air. The laser-generated plume of smoke was evacuated with the Stackhouse Point One System laser smoke filtration system (El Segundo, Calif.) with vacuum suction settings between moderate and high (6 and 9) and the distal end of the vacuum tube placed approximately 2 cm from the area treated at a given time. The plume of smoke produced during vaporization of the cervix and vagina was evacuated via a metal cannula welded on the inner surface of the upper blade of commercially available, rough-surfaced specula (Euro-Med Inc., Alameda, Calif., and Simpson-Basye, Wilmington, Del.).

Immediately before treatment, in all patients cellular samples for dot blot hybridization (ViraPap/ViraType, LTI, Gaithersburg, Md.) were obtained with saline solution–moistened Dacron swabs that were rubbed firmly against the surfaces of the lesional tissues. Samples also were taken from normal epithelium adjacent and circumferential to lesional tissues to a distance of 5 cm. Cellular sampling for HPV detection and typing was repeated after the end of each laser treatment session from the area treated (laser crater) and the normal laser margin after wiping both areas with 5% acetic acid.

The filter hybridization was performed with reagents and methods contained in the ViraPap human papillomavirus DNA detection kit according to the manufacturer's directions.

The accuracy of these tests for detecting HPV DNA compared with the standard reference method of Southern blotting has been assessed in a separate study. Specimens from 830 patients were collected and aliquots were analyzed by ViraPap and Southern blotting. The ViraPap test had a sensitivity of 94.5% and a specificity of 95.5% (S. Challberg, LTI, personal communication). In a similar analysis of specimens from 262 patients the ViraType test had a sensitivity of 97.4% and a specificity of 95.7% compared with Southern blotting (S. Challberg, personal communication). The limits of detection of these tests are approximately 3, 1, and 3 pg for ViraPap, ViraType, and Southern blotting, respectively. For statistical analysis we used the χ^2 contingency test. A p value of 0.05 was considered significant.

Results

Thirty-four of the 43 (79%) cases tested were positive for HPV DNA (Table I). There were more acuminate (26/43) than flat (17/43) genital HPV infections. Human papillomavirus DNA positivity was higher in acuminate (24/26, 92%) than in flat (10/17, 60%) HPV infections (Table II), as well as higher in external anogenital (27/31, 80%) than in internal cervical-vaginal (7/12, 60%) lesions (Table III). There were nearly as many HPV type 6/11–positive lesions (22/34, 65%) as type 16/18– and type 30s–positive lesions (12/34, 35%) (Table II). Both the treatment fields and the surrounding 5 cm laser margins after vaporization yielded similar HPV DNA positivity (16%) (Table I). The rate of HPV DNA positivity in laser margins was lower before laser vaporization (9%) than after therapy (16%) (Table I); however, it was not statistically significant.

Comment

The results of this study indicate that carbon dioxide laser-generated energy disperses viral DNA during vaporization of genital HPV infections. This was evidenced by the presence of HPV DNA in the laser treatment fields. Although the rate of HPV DNA positivity in the surrounding 5 cm of normal epithelium before and after therapy was not statistically significant, nevertheless it was nearly twice as high after (16%) as before (9%) therapy. The results confirm and extend earlier observations on papillomavirus infections in cattle and humans.[5-7] In these experiments viral DNA was found in the plume of smoke generated by carbon dioxide laser energy during vaporization procedures in four of four (100%) bovine fibropapillomas,[7] two of seven (28.5%)[7] and five of eight (62.5%)[5] human plantar warts, and in one of five (20%) precanister filters used during laser therapy of 65 patients with anogenital HPV infections.[6] Similarly, in an earlier study seven of 20 patients (35%) had positive test results for HPV DNA in normal skin within 1.5 cm of lased anogenital condylomas or intraepithelial neoplasia.[8] The somewhat lower rate of HPV positivity in our current study and our prior study on the plume of laser smoke[6] compared with that reported by Garden et al.[7] and Sawchuk et al.[5] may largely be attributed to the different viral content of lesional tissue treated. Verruca vulgaris and bovine warts contain significantly more HPV DNA than genital warts,[9] thus providing for potentially higher rates of viral detection and contamination of treatment fields, respectively.

In our previous report[8] we interpreted our finding of HPV DNA in the laser margins as latent infection of normal skin. However, results of this study suggest that the detection of HPV DNA in normal epithelium adjacent to lesional tissue before and after laser vaporization may also be caused by or be a reflection of viral shedding and carbon dioxide laser energy–generated viral dispersion.

The biologic significance of HPV DNA in and near laser-treated fields is not clear because it is not known whether the HPV DNA detected in clinical studies is in the form of virions. Mature virions are required for the transmission and development of subsequent infections, such as genital condylomas and squamous neoplasia, and HPV DNA alone is not thought to be infectious. Unfortunately, at present there are no in vitro infectivity bioassays available for HPV. However, a sensitive in vitro bioassay for bovine papillomavirus is available.[10] With this system Sawchuk et al.[5] were able to determine that infectious bovine papillomavirus particles could be recovered from laser smoke as evidenced by their ability to induce morphologic transformation of mouse C-127 cells. In addition, in a previous HPV DNA tracing study,[8] we reported a statistically significantly ($p < 0.01$) increased likelihood for early recurrent disease (3 to 6 weeks after treatment) at or near laser margins with HPV DNA–positive normal skin adjacent to lased tissue compared with HPV DNA–negative laser margins. In this study we postulated that acute recurrences were a reflection of later expression of "latent HPV" in laser margins during periods of postlaser repair. The latter usually is completed by the sixth postlaser week. In this study we did not verify the results of our previous study.

If it is assumed that carbon dioxide laser energy dispersed HPV DNA may be responsible for acute recurrences, efforts should be made to reduce viral contamination of treatment fields as much as possible. The most cost-effective means of prevention of viral dispersion is to position the suction tube of the smoke evacuator to within ≤1 cm of the area being lased. At that distance over 98% of nonvaporized material is evacuated from the lased area.[11] The remainder of the plume of smoke and its contents may be trapped by surgical masks (Tecnol Lazer mask, Sweet Medical, Lafayette, Calif.) specifically designed for laser surgical procedures.[5]

It is possible that viral contamination may further be reduced by cleaning the treatment fields with viricidal solutions after laser procedures.

It is possible, although not proved, that the mode of

laser energy used may also influence the rates of viral dispersion. However, neither the study by Garden et al.[7] nor our previous study on precanister filters[6] were able to establish a relationship between the mode of carbon dioxide laser energy used and the rates of viral contamination of treatment fields. In both studies intermittent to continuous-pulse mode with focused and defocused beams were used with power densities ranging between 500 and 5000 W/cm.[2] Regardless of the lasing modality used, HPV DNA was present in treatment fields or the plume of smoke.

We did not study the super-pulse mode with very short exposure times. It may be useful to conduct experiments with different modes of laser energy delivery systems including super-pulse, and with the use of viricidal cleaning solutions to determine if either or both will diminish HPV DNA contamination rates of treatment fields and, perhaps, lower recurrence rates and better treatment results.

Emergency treatment with recombinant tissue plasminogen activator of pulmonary embolism in a pregnant woman with antithrombin III deficiency

F. Baudo, MD,[a] T. M. Caimi,[a] R. Redaelli, PhD,[a] A. M. Nosari, MD,[a] M. Mauri, MD,[b] G. Leonardi, MD,[b] and F. deCataldo, MD[a]

Milan, Italy

Thromboembolic complications during pregnancy are frequent in patients with congenital antithrombin III deficiency. We report on a 29-year-old patient with congenital antithrombin III deficiency and severe pulmonary embolism treated with recombinant tissue plasminogen activator. The diagnosis of antithrombin deficiency is retrospective. This case indicates that the risk of thrombolytic therapy in this clinical setting might have been overemphasized. (Am J Obstet Gynecol 1990;163:1274-5.)

Key words: Pulmonary embolism in pregnancy, recombinant tissue plasminogen activator therapy

6/1/21110

Thromboembolic complications during pregnancy are frequent in patients with congenital antithrombin III deficiency: 70% according to Hellgren et al.[1] Data on thrombolytic therapy for pulmonary embolism in pregnancy are scant and equivocal. It is generally accepted that the use of thrombolytic agents carries a high

risk of placental bleeding and fetal death and that their use should be restricted to cases of massive pulmonary embolism not amenable to surgical treatment. The article by Declos et al.[2] is at variance with this view. They treated a 19-year-old pregnant woman with pulmonary embolism with urokinase and obtained good therapeutic response without significant side effects. We report on a patient with congenital antithrombin III deficiency and severe pulmonary embolism treated with recombinant tissue plasminogen activator (Boehringer Ingelheim, Ridgefield, Conn.). The diagnosis of antithrombin III deficiency is retrospective.

The patient, a 29-year-old woman in week 35 of pregnancy, was admitted to the Intensive Care Unit because of dyspnea and tachycardia of acute onset. Arterial gas analysis showed P_{O_2}, 63.9 mm Hg; P_{CO_2}, 29.6 mm Hg; and arterial pulmonary pressure 60.0 mm Hg (n.v. 18 to 26 mm Hg). Pulmonary scintigraphy showed almost complete absence of perfusion of the right lung and hypoperfusion of the lower two thirds of the left lung. A diagnosis of pulmonary embolism was made.

Treatment was a 3-hour intravenous infusion of 100 mg of recombinant tissue plasminogen activator followed by 20,000 U/day of sodium heparin in a continuous intravenous infusion. Almost complete reperfusion of the involved areas was documented by pulmonary scintigraphy at the end of recombinant tissue plasminogen activator infusion. The following morning, 20 hours after the end of the recombinant tissue plasminogen activator infusion, the patient was delivered of a male infant by cesarean section. Surgery was uneventful. No placental bleeding occurred. At surgery the coagulation laboratory data were consistent with heparin therapy: activated partial thromboplastin time ratio, 1.90; thrombin time ratio, 1.77; reptilase time ratio, 1.03, and fibrinogen, 2.2 gm/L. The patient was discharged on day 15 on oral anticoagulant therapy (warfarin). The patient has a type I antithrombin III deficiency, concordant reduction of antithrombin III activity and antigen (0.53 U/ml) with a normal crossed immunoelectrophoresis pattern.

The newborn had the clinical picture of acute respiratory distress syndrome without bleeding signs. The hemostatic parameters were consistent with prematurity (thrombin time ratio, 1.05; prothrombin time ratio, 1.66; activated partial thromboplastin time ratio, 2.19; fibrinogen, 0.9 gm/L; prothrombin, 19%; proaccelerin, 14%; proconvertin, 17%; antihemophilic factor, 19%; plasma thromboplastin component, 14%; Stuart factor, 22%; antithrombin III, 16%; and fibrinogen degradation product 8 μg/ml). He died on day 14. Autopsy showed intracerebral, intracerebellar, and subarachnoid hemorrhages commonly found in premature infants who die of adult respiratory distress syndrome, unrelated to the thrombolytic therapy.

The patient's mother died at the age of 29 because of postpartum pulmonary embolism. The patient's father has a normal antithrombin III level.

The case reported by Declos et al.[2] and our own indicate that the risk of thrombolytic therapy in this clinical setting might have been overemphasized.

Pulmonary embolism is a major cause of maternal death even in women without hereditary deficiencies that predispose patients to thrombosis.

Collagen metabolism in gynecologic patients: Changes in the concentration of the aminoterminal propeptide of type III procollagen in serum

Ulla Puistola, MD, PhD,[a] Leila Risteli, MD, PhD,[b] Juha Risteli, MD, PhD,[c] and Antti Kauppila, MD[a]

Oulu, Finland

We have previously found the serum concentration of the aminoterminal propeptide of type III procollagen, an indicator of collagen metabolism, to be increased in advanced ovarian cancer. In this study we measured the serum aminoterminal propeptide of type III procollagen concentration in healthy women during the menstrual cycle and in patients with salpingo-oophoritis, leiomyomas, endometriosis, and benign ovarian tumors. The concentration was higher in the luteal phase than that in the follicular phase, suggesting an association of collagen metabolism with ovarian steroid hormones. Severe salpingo-oophoritis increased the serum level of the aminoterminal propeptide of type III procollagen with a decrease to normal during recovery. Elevated values were occasionally seen in endometriosis and leiomyomas. These findings indicate that the aminoterminal propeptide of type III procollagen is a relatively unspecific indicator of ovarian carcinoma. (Am J Obstet Gynecol 1990;163:1276-81.)

Key words: Menstrual cycle, endometriosis, ovarian cysts, salpingo-oophoritis, aminoterminal propeptide of type III procollagen

Type III procollagen is one of the most abundant constituents of interstitial connective tissue, and comprises about 20% of the collagenous framework of both the myometrium and the cervix.[1] It is synthesized in the form of a larger precursor protein, known as type III procollagen, which contains additional peptide extentions at both ends. These sequences are known as the aminoterminal and carboxyterminal propeptides of type III procollagen.

The aminoterminal propeptide of type III procollagen, measurable in serum by radioimmunoassay,[2, 3] can be set free from the procollagen molecules during collagen synthesis, but it can also remain attached to the rest of the molecule and thus be incorporated into collagen fibers. Thus the serum aminoterminal propeptide of type III procollagen antigens can partly be derived from the de novo synthesis of type III collagen and partly from the turnover of this collagen.[4, 5] The aminoterminal propeptide of type III procollagen test has been found useful in the follow-up of ovarian cancer patients in whom elevated aminoterminal propeptide of type III procollagen concentrations in serum are frequently found, which closely correlate with the clinical behavior of the disease.[6, 7] During pregnancy the aminoterminal propeptide of type III procollagen concentration in serum increases toward term, probably reflecting the increased connective tissue metabolism in the uterofetoplacental compartment.[8]

The serum concentration of the tumor marker CA 125 is increased in some nonmalignant gynecologic diseases (e.g., endometriosis and inflammatory diseases) as well as during pregnancy, and it varies somewhat according to the phase of the menstrual cycle.[9] To fully judge the usefulness of the aminoterminal propeptide of type III procollagen measurement as a tumor marker complementary to CA 125, we evaluated the expression of the aminoterminal propeptide of type III procollagen in several nonmalignant gynecologic diseases. This study reports our findings on patients with endometriosis, salpingo-oophoritis, leiomyomas, ovarian cysts, and cystadenomas. In addition, the variation in the aminoterminal propeptide of type III procollagen concentration during the normal menstrual cycle was assessed.

Material and methods

Patients. Ten normally menstruating healthy women, ages 20 to 25 years, were followed up with repeated aminoterminal propeptide of type III procollagen measurements during one menstrual cycle. The serum samples were otherwise obtained every 2 days, but during the periovulatory time they were taken daily. Follicle maturation was estimated by ultrasonographic examination.

Twenty patients with salpingo-oophoritis were followed up in the hospital for 3 to 18 days, depending on the severity of the disease. Blood samples for the measurements of the aminoterminal propeptide of type III procollagen, C-reactive protein, and erythrocyte sedimentation rate were obtained every 2 or 3 days.

For preoperative serum aminoterminal propeptide of type III procollagen analysis, blood samples were obtained from 18 patients with uterine leiomyomas, 36 patients with ovarian cysts, 18 patients with ovarian cystadenomas, and 97 patients with endometriosis.

None of the subjects studied had any other disease including hepatic, rheumatic, or malignant diseases that could influence the serum aminoterminal propeptide of type III procollagen concentration.

All blood samples were obtained with the patients' permission and the research was carried out according to the provisions of the Declaration of Helsinki. The serum samples were stored frozen at −20° C until analyzed.

Radioimmunoassay for the aminoterminal propeptide of type III procollagen. The concentration of the aminoterminal propeptide of type III procollagen was measured in duplicate 200 μl serum samples with a recently described equilibrium radioimmunoassay.[3] The solid phase second antibody separation reagent was kindly provided by Farmos Diagnostica (SF-90460, Oulunsalo, Finland). The sensitivity of the test was 0.2 μg/L. Both the intraassay and the interassay variations were <5% at the concentrations found during the study. The reference interval (mean ± 2 SD) for healthy adults is 1.7 to 4.2 μg/L with no difference between men and women. The concentration is independent of age in adults.

Statistical analyses. A one-way analysis of variance was used to analyze the statistical significances of the differences between different groups. The significance was then tested with a modified Student t test with calculation of the critical t value by the Bonferroni method.

For comparison of the serum aminoterminal propeptide of type III procollagen concentrations in the different phases of the menstrual cycle we calculated the mean values for the follicular, periovulatory, and luteal phases (cycle days 1 to 10, 11 to 15, and 16 to 28, respectively) for each subject. The percentage of deviation of each individual value from the total individual mean was determined, and this percentage was the variable used in the statistical treatment of the results.

Results

In 10 healthy women who were followed up throughout one menstrual cycle the concentration of the aminoterminal propeptide of type III procollagen in serum varied significantly during the menstrual cycle (Fig. 1, *A* and *B*). The concentrations measured remained within the reference interval, but were somewhat lower in the follicular phase (days 1 to 10), increased toward ovulation (days 11 to 15), and elevated during the luteal phase (days 16 to 28). The difference between the follicular and the luteal phases was statistically significant ($p < 0.001$; Fig. 1, *B*).

Twelve of 20 patients who had salpingo-oophoritis had a severe disease with elevated erythrocyte sedimentation rate and C-reactive protein with accumulation of purulent fluid in the pelvic cavity. The serum concentration of the aminoterminal propeptide of type III procollagen exceeded the reference interval in eight patients; seven of them had a severe infection. After a slower increase than those seen in erythrocyte sedimentation rate or C-reactive protein, the serum aminoterminal propeptide of type III procollagen changes followed closely the behavior of these two indicators of the acute phase reaction (Fig. 2).

The 97 patients with endometriosis were grouped according to FIGO (International Federation of Gynecology and Obstetrics) staging of the disease (Fig. 3). The median concentrations of serum aminoterminal propeptide of type III procollagen were 3.7 μg/L in stage I (range, 2.1 to 7.6 μg/L; $n = 54$), 3.3 μg/L in stage II (range, 2.0 to 6.1 μg/L; $n = 24$), and 3.9 μg/L in stages III and IV combined (range, 2.0 to 6.2 μg/L; $n = 19$). The upper limit of the reference interval was exceeded by 13, three, and six patients, respectively, or in 23% of all. There were no significant differences between the groups, and none of the groups differed significantly from the reference population, which consisted of healthy Finnish blood donors.[3]

Of the 18 patients with uterine fibroids from whom serum samples were obtained before operation, six had elevated serum concentrations of the aminoterminal propeptide of type III procollagen (mean, 4.1 μg/L; range, 3.6 to 7.6 μg/L). The value did not correlate with the age of the patient or with the size of the fibroid.

In the group of 36 patients with benign ovarian cysts, there were no elevated aminoterminal propeptide of type III procollagen concentrations. The median value

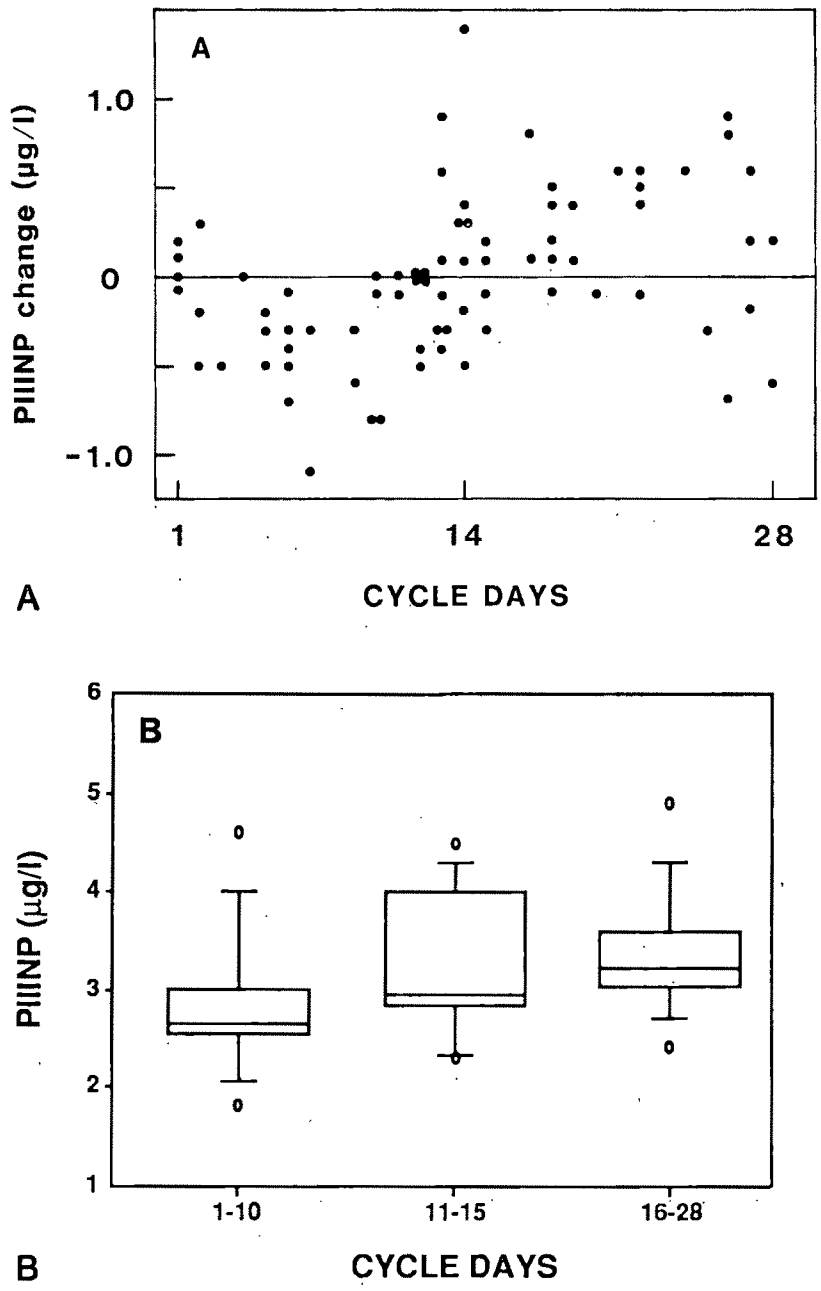

Fig. 1. Variation of aminoterminal propeptide of type III procollagen *(PIIINP)* concentration in serum during normal menstrual cycle. For detailed description of follow-up see Material and methods section. **A,** Deviation of individual values from overall mean value, calculated for each subject. **B,** Box and whiskers plot analysis. was 2.5 µg/L and the range was 1.4 to 4.1 µg/L. Of the 14 patients with a benign cystadenoma, only one had a aminoterminal propeptide of type III procollagen concentration above the reference range (5.8 µg/L). In this group the median was also 2.5 µg/L with a range of 1.6 to 5.8 µg/L.

Comment

The concentration of the aminoterminal propeptide of type III procollagen in serum is frequently increased in up to 83% of patients with advanced ovarian cancer and correlates with the clinical course of the disease.[6,7] In addition, it is elevated in about 40% of pa-

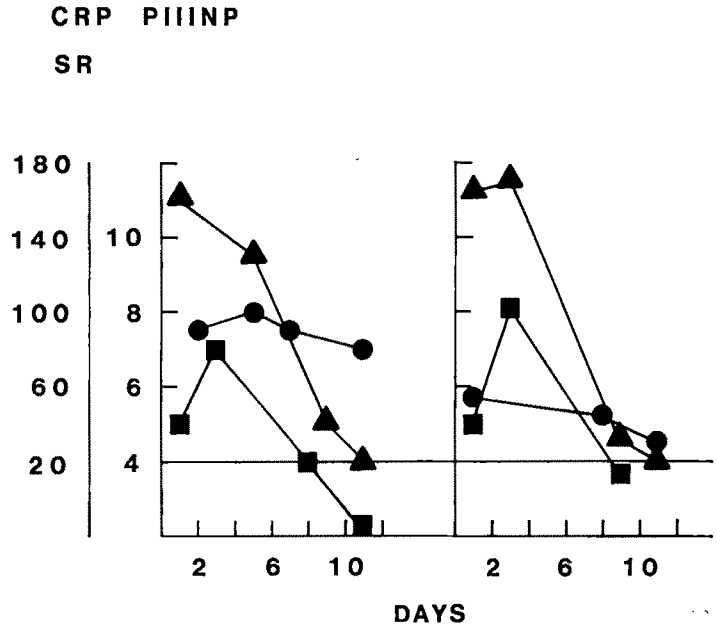

Fig. 2. Follow-up of two patients with severe salpingo-oophoritis. ▲ indicates C-reactive protein *(CRP)* (milligrams per liter), ● erythrocyte sedimentation rate *(SR)* (millimeters per hour) and ■ aminoterminal propeptide of type III procollagen *(PIIINP)* (micrograms per liter). *Horizontal line* indicates upper limits of reference intervals of these three parameters. Note different scales on left.

tients with advanced endometrial or cervical carcinoma.[10] The present study was undertaken to test whether the results of the aminoterminal propeptide of type III procollagen test are affected by other gynecologic diseases. This kind of information is essential for the correct clinical interpretation of elevated concentrations in patients with malignant tumors.

The nonmalignant disease that was most frequently associated with a significantly increased aminoterminal propeptide of type III procollagen concentration in serum was severe salpingo-oophoritis. In this septic condition the serum aminoterminal propeptide of type III procollagen concentration resembled the acute phase parameters of C-reactive protein and erythrocyte sedimentation rate in its behavior. A similar increase was found earlier in patients with septic wound infections.[11] In the latter case the serum antigen was characterized and found to be predominantly of larger size than the aminoterminal propeptide set free during synthesis of type III collagen. This finding suggests that the serum aminoterminal propeptide of type III procollagen in severe infections is derived from the partial degradation of type III collagen fibers in the affected tissues. Inasmuch as some aminoterminal propeptide is found on the surface of such fibers,[12] it is probably relatively sensitive toward locally increased proteolytic activity.

Like the CA 125 antigen, the aminoterminal propeptide of type III procollagen seems not to be affected by nonmalignant ovarian lesions. This is an important finding and it stresses the usefulness of the aminoterminal propeptide of type III procollagen test in the differential diagnosis between benign and malignant ovarian lesions.

A total of 23% of patients with endometriosis had serum aminoterminal propeptide of type III procollagen concentrations above the reference interval; however, there was no association between the elevations and the severity of the disease. CA 125 is also increased in about 25% of these patients, but in contrast to the aminoterminal propeptide of type III procollagen, the degree of elevation is related to severity of endometriosis.[9, 13] The reasons for the skewed distribution of the aminoterminal propeptide of type III procollagen values in our patients with endometriosis is not clear. It is possible that in this condition the aminoterminal propeptide of type III procollagen is derived from a reaction of peritoneal cells, including fibroblasts, to local irritation, a mechanism that could also function in salpingo-oophoritis. This may also be true for the increase in serum aminoterminal propeptide of type III procollagen in patients with uterine leiomyomas. Another source in this case might be the increased collagen metabolism inside the tumor.

Hormonal regulation of extracellular matrix metabolism is a clinically important but little investigated topic. The occurrence of the aminoterminal propeptide of type III procollagen antigen has been demonstrated

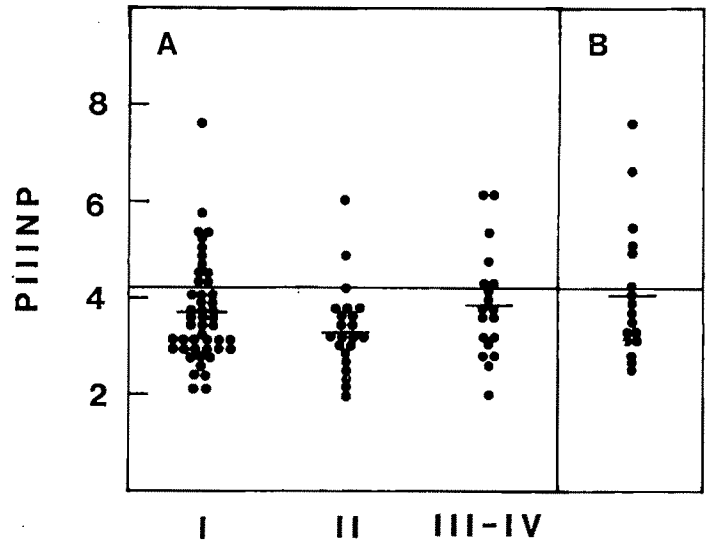

Fig. 3. Aminoterminal propeptide of type III procollagen *(PIIINP)* concentration (micrograms per liter) in serum of patients with endometriosis **(A)** and uterine leiomyomas **(B).** *I* to *IV* indicate stages of endometriosis according to FIGO (International Federation of Gynecology and Obstetrics) staging. *Continuous horizontal line* indicates upper limit of reference interval; *short horizontal lines* denote means for each group.

in ovarian follicular fluid, where its concentration correlates negatively with the progesterone content of the fluid.[14] We now found a statistically significant elevation of the aminoterminal propeptide of type III procollagen concentration in serum between the follicular and luteal phases of a normal menstrual cycle. This change, despite the concentration remaining all the time within the reference interval, was noted in each of the 10 women who underwent the study. Although the aminoterminal propeptide of type III procollagen values did not correlate with the estrogen or progesterone concentrations measured in the same blood samples, it seems obvious that the variation is a result of the hormonal changes and is brought about either by changes taking place in the endometrial connective tissue or by alterations in the matrix metabolism all over the body. It has been suggested that estrogens specifically repress the synthesis of type III procollagen in smooth muscle cells.[15] In addition, one of the principal functions of progesterone is thought to be an induction of the synthesis of stromal structures in the endometrium.

Our clinical studies revealed many similarities between CA 125 and aminoterminal propeptide of type III procollagen. Both are frequently increased in advanced ovarian carcinoma[6, 7, 9] and in some other gynecologic malignancies.[6, 9, 10] Increased concentrations of both markers are often present during pregnancy and pelvic inflammatory diseases and sometimes in endometriosis. The factors associated with the growth of gynecologic malignancies and with the inflammatory reactions of pelvic peritoneum seem to involve the regulation of the expression of both CA 125 and type III collagen.

We gratefully acknowledge the expert technical assistance of Kristiina Pekkala and Ulla Väinämö.

Why all placentas should be examined by a pathologist in 1990

Carolyn M. Salafia, MD,[a, b] and Anthony M. Vintzileos, MD[b]
Farmington, Connecticut

Placental pathology is rarely a part of the training for either obstetrician or pathologist. As a result there has been confusion regarding the potential benefits of routine placental examination. These benefits include clarification of the causes of many adverse pregnancy outcomes, improvement of the risk assessment for future pregnancies, and ascertainment of newborn risk for long-term neurodevelopment sequelae. Information on placental abnormalities may reveal the presence of chronic fetal insults and allow their differentiation from acute (peripartum) stresses. Current methods of risk assessment fail to identify the majority of pregnancies that end in prematurity, stillbirth, growth retardation, or fetal distress. We suggest that placental pathology should be a routine component of obstetric-neonatal care. (Am J Obstet Gynecol 1990;163:1282-93.)

Key words: Fetus, maternal-fetal medicine, placenta, pathology

It would surprise neither obstetricians nor pathologists if a governmental survey concluded that the single group expressing the most consistent interest in the placenta was the cosmetics industry, which purchases tons of placentas yearly for the extraction of hormones and proteins to be used in hair, face, and skin care treatments. There are several reasons for this mutual disinterest on the part of our medical colleagues. Placental and perinatal pathology is rarely a part of the residency training program for either discipline. The end result is lack of a mutual vocabulary, which leads to poor communication of relevant clinical information and frustration of both pathologist and obstetrician. The most significant problem with the pathologist is that he/she fails to appreciate the pathophysiologic features and clinical presentation of the histologic changes he/she may identify. As far as the obstetrician is concerned, he/she is most often unable to combine the clinical data with the different histologic types, which have to be merged in a clinically relevant fashion. In addition, obstetricians usually consider any information obtained from the study of the placenta to be retrospective, i.e., after the fact and therefore of no help in the prospective management of the pregnancy in question. Finally, adequate examination of the placenta requires an outlay in technical personnel and material, which, in an era in which cost-effectiveness is a major concern to all hospitals, may not be readily forthcoming.

It is our belief that examination of the placenta should be of vital interest to both obstetricians and neonatologists, as well as hospital lawyers and risk managers. The possible benefits derived from placental examination include: (1) clarification of the pathophysiologic features and significance of antepartum events detected by modern technology, as well as the relative contributions of "acute" (peripartum) and "chronic" (antepartum events of adverse neonatal outcomes; (2) improved management of subsequent pregnancies by diagnosing pathologic conditions that may have risks of recurrence or may even be preventable or treatable in subsequent pregnancies; (3) assessment of newborn risk for long-term neurodevelopmental sequelae, thus giving the opportunity to optimize long-term outcome by early and timely interventions.

This communication was therefore undertaken to address: (1) the terminology and clinical significance of gross and microscopic placental lesions, (2) the role of placental pathologic examination in differentiating between acute and chronic fetal insults, (3) the need for routine placental pathologic examinations in all preg-

nancies; and (4) the cost-effectiveness of routine placental pathologic examination.

Terminology and clinical significance of placental lesions

Gross examination (Table I)

Extraplacental membranes. The extraplacental membranes are examined for adherent blood clot, which may indicate the presence of abruptio placentae. The membranes' color may be described as "clear" (normal), cloudy, or opaque. When cloudy or opaque membranes are found, an ascending intraamniotic infection should be suspected. Membranes may also be described as green (indicating meconium staining), yellow (indicating amniotic hyperbilirubinemia) or red-brown (raising the possibility of intraamniotic bleeding). Certain bacterial infections may cause the membranes to appear green or yellow in the absence of intraamniotic pigments, but these membranes are generally also thick and opaque.

If the membranes are complete, the site of rupture should be determined by placing the hands inside the amniotic sac. The rupture site in a normal vaginal delivery should indicate the pericervical membranes. If the rupture site is at the placental margin, this suggests that the edge of the placenta may have been in the cervical area (a marginal placenta previa) or in the lower uterine segment. If the site of rupture in a vaginal delivery is >10 cm from the placental margin, it is likely that the implantation was fundal.

The membrane insertion onto the chorionic plate is described as marginal (normal), circummarginate, or circumvallate. When the membranes are inserted marginally, the chorionic plate extends to the edge of the placental disk, and the membranes are inserted at the edge of the disk. In circummarginate insertion the chorionic plate is circumscribed by a ring of fibrin. The placental disk may extend several centimeters beyond the limits of the chorionic plate. This insertion is not associated with fetal-neonatal compromise.[1] In circumvallate insertion the chorionic plate is also smaller than the placental disk, but the ring limiting the chorionic plate is a fold of extraplacental membranes (amnion, chorion, and decidua). The firm white appearance of this ring is due to ischemic necrosis of the chorion and decidua entrapped in this fold. Circumvallate insertion has been associated in our experience with chronic oligohydramnios, amnion rupture, maternal smoking, and other conditions of uterine vascular insufficiency.

Next, the amnion should be inspected carefully for the presence of amnion nodosum, a lesion seen in association with prolonged oligohydramnios of any cause. Grossly, these lesions appear as irregular lumps of granular material that cannot be easily scraped from the amnion surface.

The determination of chorionicity is very important in multiple gestations. For more information, the reader is referred to standard reviews of the subject.[1-3]

Table I. What to look for in gross placental examination

- Extraplacental membranes
  - Adherent blood clot
  - Color
  - Transparency
  - Site of rupture (relative to placental margin)
  - Insertion (marginal, circummarginate, circumvallate)
  - Amnion nodosum
  - Velamentous vessels (if present, ? intact)
  - Chorionicity (multiple gestations)
- Umbilical cord
  - Length
  - Diameter
  - Color
  - Vessel number (single artery)
  - Angioma, allantoic and omphalomesenteric remnants
  - True knots
  - Insertion (central, marginal, velamentous)
- Chorionic plate
  - Color and transparency
  - Dimensions and shape
  - Vascular pattern (velamentous vessels)
  - Subchorionic thrombi
- Maternal surface
  - Completeness
  - Adherent blood clot, placental indentation (abruptio placentae)
  - Calcifications
- Villous parenchyma
  - Infarction, intervillous thrombosis
    - Color
    - Location and dimensions
  - Chorioangioma
    - Color
    - Dimensions
    - Solitary-multiple
  - Maternal floor infarction
  - Perivillous fibrin deposition
  - Pallor

Umbilical cord

LENGTH. In term gestations the normal umbilical cord length ranges from 54 to 61 cm.[4-6] On the basis of Gardiner's calculation,[7] 32 cm is considered the minimal length of the cord in a term infant. Abnormally short cords have been observed in conditions of restricted fetal movements, such as in oligohydramnios, fetal paralysis, etc.[8] Long umbilical cords (arbitrarily set at >100 cm[6]) may be associated with multiple nuchal cords, cord prolapse,[9] or funic presentation.

DIAMETER. The umbilical cord diameter is usually larger where it is closer to the fetus and where it might be expected to have the greatest arterial pressure. Variations in umbilical cord diameter observed after the cessation of umbilical blood flow reflect to a large degree changes in the volume of Wharton's jelly. Both segmental lack of Wharton's jelly and lack of Wharton's jelly before insertion of the umbilical cord onto the chorionic plate ("furcate" or "forked" insertion) have

been seen in association with fetal compromise or death.[10] An increase in Wharton's jelly may appear as edema, with the umbilical cord taking on a milky color. Edema of the cord may be observed in cases of intraamniotic infection or a functionally significant true knot, as well as in cases of maternal diabetes and Rh isoimmunization.[11] In situations of fetal volume depletion, such as preeclampsia or intrauterine growth retardation, Wharton's jelly will be water depleted, and the surface of the umbilical cord will appear wrinkled (like "dishpan hands").

COLOR. The umbilical cord may also be stained by the same intraamniotic pigments (meconium, bilirubin, hemosiderin) that may stain the membranes. In cases of intrauterine fetal death, the umbilical cord will become progressively red-brown, as a result of hemolysis of fetal blood in the umbilical vessels. In cases of intraamniotic candidiasis, yellow plaques on the surface of the umbilical cord should alert the pathologist to the possibility of candidal abscesses.

UMBILICAL VESSELS. The normal umbilical cord contains two small caliber arteries and one larger caliber vein. Absence of an umbilical artery was originally reported to be significantly more frequent among infants with congenital anomalies, especially of the urinary tract, as well as with tracheoesophageal fistulas and central nervous system changes.[11] However, a single umbilical artery is also observed in clinically normal infants, and most frequently in our experience it is the only abnormality found. While Altshuler et al.[12] have shown no significant changes in incidences of fetal anomalies in cases of arterial aplasia versus arterial atrophy, we have observed several instances in which fusion of the umbilical arteries was confined to a single area of umbilical cord in otherwise normal infants. The relationship of a single umbilical artery to fetal anomalies may vary, depending on whether two functional umbilical arteries are present intraabdominally.[12]

OTHER UMBILICAL STRUCTURES. Other structures present in the umbilical cord may create the appearance of accessory vessels. Four or even five vessels may be apparent on cross section of the umbilical cord. While this may represent an area of varicosity, it may also be due to persistent omphalomesenteric vessels. A persistent allantoic duct may also appear to be a "fourth vessel." Umbilical angiomas are not infrequent microscopic findings but rarely are grossly recognizable or clinically relevant. Unusual lesions of the umbilical cord have been described, including teratomas.[1, 11, 13, 14]

TRUE KNOTS. True knots of the umbilical cord must be distinguished from "false knots" or varicosities, distinction generally made with ease. Cessation of blood flow through the umbilical cord by an acute tightening of a knot is a rare event if the blood flow through the umbilical cord has previously been normal. Tightening of a knot leading to restricted flow occurs only after the flow has already become abnormally slow or when the cord has already demonstrated decreased intravascular pressure. The mechanics and arrangement of the umbilical cord vessels are such that the cord acts as erectile tissue, which is not deformable under situations of high-volume blood flow.[15] After flow has ceased (i.e., stillbirth), a cord knot will often tighten during the labor and delivery, thus giving the false impression that obstruction to umbilical blood flow was the cause of fetal death. The clinical significance of a cord knot therefore must be carefully investigated. If a cord knot was primarily responsible for alterations in umbilical flow, several changes should be grossly apparent, depending on whether the changes were chronic or acute. If Wharton's jelly is tubular and not deformed, such a knot should be considered to be postmortem and therefore of dubious clinical significance. If the knot was tight in utero, umbilical venous distention should be present on the placental side of the knot, and edema, as a result of increased arterial pressure, should be present on the fetal side of the knot. If cord vessels are acutely obstructed by the knot while the fetal heart is actively beating, umbilical arterial hemorrhages on the fetal side of the knot and venous hemorrhage on the placental side of the knot might also be observed. In situations of chronic alteration of blood flow, both grossly and microscopically, thrombi may be observed as secondary events. Knots tightened postmortem should not have changes of edema, vascular distention, or disruption, and the proximal and distal segments of the cord should have a similar appearance.

UMBILICAL CORD INSERTION. The umbilical cord insertion may be described as central, eccentric, marginal, or velamentous relative to the chorionic plate. Eccentric cord insertions are associated with multiple gestations or uterine septa. Marginal and velamentous insertions may pose hazards to the fetus.[16] A marginally inserted cord may be more poorly supported than one based on the chorionic plate and more susceptible to compression from mechanical pressures. We have observed several cases of growth failure, as well as stillbirth, after external cephalic version when a marginal cord insertion was present. Placental abnormality was consistent with intermittent instability or changes in volume and pressure of flow within the placental circulation. The dangers of a velamentous cord insertion are well known. Velamentous vessels running in the placental membranes are also more susceptible to mechanical compression and, more important, to tearing during labor and delivery. The condition known as vasa previa, when velamentous vessels cross the cervical os, may be fatal to the fetus if not detected before membrane rupture.

Chorionic plate. The chorionic plate is composed of

amnion and the vascular chorion, within which there are arteries ramifying from the umbilical vessels and veins draining the placental villi. Inspection of the chorionic plate may reveal several characteristics of the extraplacental membranes, such as color and transparency. Abnormalities of insertion of the extraplacental membranes may result in abnormalities of the chorionic plate. A "battledore" placenta is one with an extremely eccentric cord and is of no significance unless velamentous vessels exist. White plaques may be visible through the chorionic plate. These are areas of subchorionic thrombi. They are more frequent in placentas of mothers who smoke.[17]

Maternal surface. Gross defects may indicate significant volumes of retained villous placenta. Clinically, the possibility of retained villous tissues may alert the obstetrician to patients at risk for postpartum hemorrhage or endometritis.

The maternal surface should also be examined for the presence of adherent blood clot. Any adherent blood must be considered as potentially relating to acute abruptio placentae, and when the clinical suspicion warrants, villous tissue adjacent to areas of blood clot should be examined for microscopic evidence of acute alterations in intervillous flow. The nearby maternal surface should be inspected for evidence of depression or compression of the villous placenta. A section through the villi subjacent to an area of adherent retroplacental blood should be examined microscopically for changes indicative of early infarction or focal trophoblast ischemia.

Villous parenchyma. The placental villi should be examined by serial sections of the placenta, perpendicular to the maternal surface and chorionic plate, at approximately 1 cm intervals. Both surfaces of each cut should be examined for the presence of the abnormalities described here.

INFARCTION. Recent (acute) infarctions may be difficult to distinguish from viable placenta but will generally be firmer and have a slightly different hue than adjacent viable areas. Old infarcts will be tan-white. All lesions suspected grossly to be infarctions should have this impression confirmed microscopically, since other lesions (for instance, infarcted chorioangiomas) may grossly resemble placental infarctions. The approximate size of the infarct should be noted. In a series of 500 consecutive placentas delivered of uncomplicated pregnancies at term, we observed a 10% incidence of placental infarction, and 90% of these lesions occupied <1 cm cubic volume.

The location of the lesion should be described as marginal (within 2 to 3 cm of the edge of the placenta) or central. In our experience 90% of placental infarctions in normal term deliveries are marginal. Whether a lesion is juxtabasal, subchorionic, or located centrally within the villous parenchyma is also important. The most likely location for ischemic villous death in the event of decidual vascular occlusion is at the maternal surface. Lesions grossly having the appearance of infarctions, which are located separate from the basal plate, should be carefully examined microscopically for the presence of associated acute or chronic villous inflammation.

INTERVILLOUS THROMBOSIS. In the subchorionic area blood flow is turbulent.[1] If spiral arterial flow is disturbed, subchorionic blood flow might become stagnant, possibly leading to subchorionic thrombosis. Subchorionic thromboses are common in term pregnancies and appear as laminated, white-tan plaques that can be seen through the chorionic plate. Generally, these lesions will be <5 to 8 mm in thickness and occupy less than 2 cm.[2] of the chorionic plate. Plaques of subchorionic fibrin have been observed more frequently among smokers,[17] who have increased numbers of platelets and increased platelet adhesiveness.[18] Intervillous thromboses that are distant from the maternal surface are usually composed of mixed maternal and fetal blood, and they are more common in cases of rhesus isoimmunization.[2] Intervillous thromboses close to the maternal surface are predominantly composed of maternal blood and may represent the effects of local disruption of spiral arterial flow.[19] While the clinical significance of intervillous thromboses has not been entirely understood, we have observed such thrombi, generally multiple and parabasal, in cases of preterm rupture of membranes with abnormal fetal biophysial assessment.

CHORIOANGIOMA (PLACENTAL HEMANGIOMA). These lesions may frequently be confused with intervillous thrombosis or placental infarction. Depending on the viability and vascularity of the lesion, they may appear as dark red-brown or white-yellow, sharply circumscribed lesions. Chorioangiomas may be solitary or multiple. If multiple, they may occasionally be associated with fetal angiomas in brain, liver, or other viscera.[20] They may also cause fetal compromise by their ability to function as shunts. Massive or multiple chorioangiomas may be found in cases of intrauterine death with or without fetal hydrops. Solitary lesions may present clinically as fetal tachycardia, as fetal distress, or, when infarcted, with mild degrees of neonatal thrombocytopenia, as a result of increased platelet consumption within the vascular tumor. Placental chorioangiomas have been assocated with extremely elevated maternal serum α-fetoprotein values and may be detected ultrasonographically.

MATERNAL FLOOR INFARCTION. This particular lesion is discussed separate from placental infarction because of its different etiology. Grossly, the lesion is generally a bandlike area of white-tan tissue running along the

Table II. What to look for in microscopic examination of placenta

Noninflammatory changes of amnion
Amnion nodosum
Meconium histiocytosis
Acute inflammatory changes
Pattern of spread of organism (extraamniotic or intraamniotic)
Maternal versus fetal inflammatory response
Discordance between maternal-fetal inflammatory responses
Infarction, intervillous thrombosis
Age
Associated pathologic condition (chronic villitis, decidual thrombosis, etc.)
Chronic villitis
Type of cellular infiltrate
Presence of intervillositis
Volume of affected tissue (grade)
Associated features (vasculitis, intravascular thrombi, hemorrhagic endovasculitis, etc.)
Hemorrhagic endovasculitis
Type of vessel(s) involved (chorionic, major stem, etc.)
Volume of affected tissue (grade)
Associated changes (chronic villitis, placental intravascular thrombi, etc.)
Placental intravascular thrombi
Type of vessel(s) involved (chorionic, major stem, etc.)
Number of involved vessels
Associated features (vasculitis, hemorrhagic endovasculitis, etc.)
Trophoblast degenerative knots
Proportion normal, increased, or decreased relative to gestational age
Diffuse or focal
Associated changes (abnormal villous fibrosis or vascularity, decidual vasculopathy, etc.)
Perivillous fibrin deposition and fibrinoid necrosis
Proportion normal, increased, or decreased relative to gestational age
Diffuse or focal
Associated changes (X-cell proliferation, acute inflammation, villous and decidual pathologic conditions)
Erythroblastosis and villous edema
Proportion of nucleated-anucleate erythrocytes (relative to gestational age)
Proportion of affected villi (edema)
Severity of edema (diameter of affected villi relative to gestational age)
Associated changes (acute or chronic inflammation, decidual vasculopathy, abruptio placentae)

fetomaternal interface at the basal plate. The area of involvement may be very narrow or may involve all but subchorionic areas of placenta. Maternal floor infarction has been reported to be a cause of repeated poor pregnancy outcome[21] and has recently been suggested to be of immunologic origin.[22] Its identification is clinically relevant because of the reported potential for recurrence in subsequent pregnancies.

PERIVILLOUS FIBRIN DEPOSITION. The normal villous parenchyma on cross section is dark red and finely granular. Occasionally, white glistening bands of connective tissue carrying the major branches of the fetal stem vessels may be identified. Perivillous fibrin appears as an irregular tan-brown granular material, which appears to be deposited with irregular outlines, and it is located away from the maternal sruface, which allows this lesion to be differentiated from more infarctions. This process is considered to indicate a local ischemic process. In our experience, focal perivillous fibrin deposition is found in 5% to 10% of normal term placentas.

Microscopic examination (Table II)

Noninflammatory changes of the amnion. The normal histologic appearance of the amnion is usually composed of three elements: a low cuboidal epithelium, a dense acellular connective tissue layer, and a loose connective tissue layer with scattered spindle cells that have elongated nuclei and sparse cytoplasm,[23] which phenotypically are macrophages. In severe and prolonged cases of oligohydramnios, squamous debris is ground into the amnion by fetal movements. This is precisely the histologic appearance of amnion nodosum. In this lesion keratinized squamous debris is present in lumps on the amnion surface. The epithelium is not present below the deposit, but there will be reepithelialization of the surface of the squamous deposit to varying degrees. Amnion nodosum is more commonly seen over the chorionic plate than in the reflected membranes. Not surprisingly, it is a rare lesion outside the setting of renal agenesis or prolonged rupture of membranes with persistent oligohydramnios of at least 1 week's duration.

Examination of the amnion and chorion for the presence of meconium-filled macrophages may also provide information regarding the duration of exposure of the membranes to meconium before delivery. Meconium in amniotic fluid diffuses across the amnion and is phagocytosed by the spindle cells of the deep connective tissue layer. After meconium phagocytosis these cells take on a plump shape more characteristic of a macrophage. It is presumed that the number of meconium-laden cells is related to the volume of meconium diffusing from the amniotic fluid and that the depth of diffusion through the amnion, chorion, or decidua is likely related to the duration of exposure to meconium.

Acute placental inflammation. As discussed above, intraamniotic infection may be suspected by gross examination of the umbilical cord, membranes, and chorionic late. The gross diagnosis of intraamniotic infection, however, requires microscopic examination to confirm gross diagnosis and to provide information as to duration-severity and occasionally type of organism. We routinely examine the following sections: two samples of umbilical cord (one close to the distal end of the cord and one from within 10 cm of the insertion on the chorionic plate), two samples of extraplacental membranes (one from the edge of the site of rupture, when identifiable, and one from a membrane roll ex-

tending from the site of rupture to the placental margin), and at least one sample of chorionic plate including chorionic vessels. This method allows us to answer the following questions: Is there an inflammatory process in the pericervical tissues of the site of rupture? If yes, did the inflammation spread laterally through the decidua and therefore remain extraamniotic, or did the inflammation extend into the amniotic fluid? If an intraamniotic inflammation is evident, is there a fetal response (umbilical vasculitis and/or funisitis)? The relevance of these questions to clinical situations such as premature rupture of membranes, preterm labor and delivery, and fetal jeopardy is clear. Patterns of inflammation within the extraplacental membranes may provide clues as to the pathway of the infectious spread.

A discordance between the maternal and fetal components of the inflammatory response may alert the pathologist to the possible involvement of organisms such as group B streptococcus. Pandey et al.[24] clearly demonstrated that certain women who are chronic carriers of this organism have abnormal humoral and cellular immune responses to the streptococcus. When group B streptococcus is involved in an intraamniotic infection in women with absent immune response, the histologic features would be characterized by absent or minimal maternal inflammatory response (in extraplacental membranes and chorionic plate) and a well-developed fetal response (in umbilical cord and chorionic vessels). In the absence of any defensive maternal participation, the fetus-neonate is at risk for severe infectious complications. Indeed this pattern has been observed in cases of catastrophic early-onset neonatal streptococcal sepsis and is commonly observed in women with several children, all of whom suffered neonatal streptococcal sepsis. While there is controversy as to whether women should have cultures performed and/or be treated for streptococcal colonization, it is our opinion that patients with histologic evidence of an inability to mount an immune response to this organism should be considered as candidates for treatment since they are at high risk for developing neonatal sepsis. Only placental examination will identify this group of patients.

Infarction. Microscopically, these lesions will show frank villous necrosis, involving trophoblast, stroma, and endothelia. Recent lesions may show a striking excess of syncytial knotting and early necrosis of the trophoblast. Villous stromal hemorrhage, a marker of placental hypoxia,[25] may be seen in early lesions. Chronic lesions will show an already established villous necrosis and the presence of "ghost villi." These "ghost villi" appear as pale pink eosinophilic bodies with complete loss of all nuclear detail. These lesions are probably at least 7 days old.

Intervillous thrombosis. Microscopically, thromboses are often very bland lesions, consisting of variable combinations of sheets of erythrocytes and bands of organized fibrin. The proportions of erythrocytes and fibrin will vary with the age of the lesion. Acute lesions appear as sheets of erythrocytes apparently pushing villi aside and distorting the normal architecture of the intervillous space. Chronic lesions show uniform eosinophilic bands of fibrin. Occasionally, chronic villitis may be seen at or near a thrombus. In this situation, one may ask whether the chronic inflammation and villous damage were the stimuli of local coagulation. Hemorrhagic endovasculitis may also be seen in villi nearby or at the edge of a thrombus.

Chronic villitis. Chronic villitis is defined as a chronic inflammatory infiltrate of the placental villi composed of plasma cells, lymphocytes, and histiocytes or macrophages. It is unknown if the villous infiltrate is of maternal origin, fetal origin, or a mixed response. Known congenital TORCH infections (toxoplasmosis, rubella, cytomegalovirus, herpes simplex) are characteristically associated with chronic villositis,[26] while certain histologic features have been proposed to be "pathognomonic" of certain viral entitities.[27] Viruses are rarely isolated from such placentas. The presence of extensive vascular damage, together with stromal hemosiderosis and calcification, suggests cytomegalovirus, while a massive proliferation of placental Hofbauer cells may be more likely to be associated with congenital syphilis.[28] It has been recently suggested that chronic villitis is also associated with maternal immunopathologic states.[29, 30] Chronic villitis with dense chronic intervillositis may be associated with recurrent poor pregnancy outcome[31] and with absent maternal antipaternal blocking factors. Clinical information regarding parity, intercurrent diseases, and past pregnancy outcome are of paramount importance to the appropriate interpretation of this lesion.

The means by which chronic villitis is associated with intrauterine growth retardation has been proposed to be secondary to viral impairment of fetal cellular divisions leading to decreased cell number and a smaller neonate.[32] This has been used to explain the lack of correlation between the degree of placental compromise (amount of villi inflamed) and the degree of fetal compromise. We have demonstrated an association between increased frequency of chronic villitis and decreased ponderal indices in a series of growth-retarded infants delivered at term. In the same study primiparity and chronic villitis were related, independently of birth weight. Low ponderal index indicates a late onset of intrauterine deprivation. To explain these relationships we must propose that there is a predisposition to third-trimester viral infection among primiparous women or that chronic villitis may indicate the presence of a maternal inflammatory-immunologic response to the fetal

allograft. This inflammatory-immunologic response may lead to fetal compromise by alterations in placental function. The possible role of placental macrophages in these important placental functions is currently under investigation in our laboratory.

A sparse chronic villitis involving only occasional anchoring villi is frequently seen in placentas from uncomplicated term deliveries. We have seen the presence of a dense infiltrate, possibly including plasma cells, involving many if not all of the anchoring villi in preeclampsia, idiopathic recurrent abruptio placentae, intrauterine growth retardation, and preterm delivery. The pattern of spread, from maternal to contiguous fetal tissues, strongly suggests an underlying abnormality in the maternal immunologic adaptation to pregnancy. When villi that are distant from the maternal surface are predominantly involved, one may suspect a hematogenous dissemination of infection, such as congenital viral infection.

We describe the relative volume of affected villi and the distribution of affected villi by using a six-point system. Grade 1 applies to a solitary focus of villitis on any one of the four samples routinely examined. Grade 2 describes two foci of villitis on the same slide or different slides. Grade 3 describes multiple foci on at least two different slides. Higher grades (up to six) are assigned on the basis of subjective assessment of percent of involved villi. In normal term placentas the rate of chronic villositis will be approximately 15%. More than 90% will be grade 1 or grade 2. In uncomplicated term deliveries we have rarely found more severe grades of villitis (grade 3 or 4).

Hemorrhagic endovasculitis. Sander et al.[33] first coined the term *hemorrhagic endovasculitis* to describe a lesion observed in cases of unexplained poor pregnancy outcome referred to the Michigan Placental Tissue Registry. This lesion may affect any or all levels of the placental circulation from chorionic vessels and fetal stem vessels to the capillaries of the terminal villi. In the larger vessels it typically appears as a vasoocclusive process with endothelial damage, fibroblast proliferation with scalloping of the vessel outline, erythrocyte fragmentation, and bleeding within the vessel wall and in the villous stroma. At the capillary level only erythrocyte fragmentation and vascular damage are present. Hemorrhagic endovasculitis was originally suggested to be of immunologic origin. However, some investigators believed that the lesion is secondary to hemodynamic instability within the placenta, as a result of association of this lesion with placental infarction.[25] Our investigations have also shown an association of hemorrhagic endovasculitis with placental infarction, chronic villitis, and placental intravascular thrombi. It is most commonly seen in preeclampsia, stillbirth, and intrauterine growth retardation. We would therefore support the interpretation of hemorrhagic endovasculitis as a lesion most frequently resulting from abnormal placental blood flow.

Placental intravascular thrombi. In the past we rarely observed thrombi within placental chorionic or stem vessels (intravascular thrombi). When placental intravascular thrombi were present, they most often were coincident with severe intraamniotic infection or with chroinic villitis. However, in 1989, approximately 10% of placentas examined in our laboratory demonstrated bland mural thrombi in placental vessels. These observations were more frequent in placentas coming from mothers who use cocaine and/or "crack" cocaine. Cocaine causes an intense vasospasm that results in endothelial damage, platelet aggregation, and thrombus formation.[34] Woods et al. have shown that fetal vessels are very sensitive to the vasoactive effects of cocaine (Woods JR, Plessinger MA, Dolkart L. Effect of cocaine upon fetal umbilical blood flow and placental vascular resistance [Abstract]. In: Proceedings of the Rochester Trophoblast Conference with the European Placenta Group, Rolduc, The Netherlands, September 1988). Chasnoff et al.[35] observed neurologic compromise in infants of mothers who ceased cocaine use during pregnancy. It is possible that cocaine can generate venous thrombi in the placenta, predisposing to a situation of chronic thromboembolism, which could chronically damage the fetal central nervous system. These possibilities deserve further investigation.

Trophoblast degenerative knots. In degenerative knots the syncytial nuclei are dark blue-black and pyknotic. Fox[36] has studied the formation of such knots in vitro, and has shown that they develop as early as 24 hours after culture in a low oxygen tension environment. From the clinical point of view these lesions are diffusely increased in situations of chronic uterine vascular insufficiency (e.g., hypertensive diseases of pregnancy) and focally increased in acute abruptio placentae.

Perivillous fibrin deposition and fibrinoid necrosis. These are discussed together as they appear somewhat similar histologically and may coexist in the same placentas. Microscopically, in perivillous fibrin deposition, eosinophilic fibrin coats the surfaces of villi, often matting them together. The villi themselves remain viable, although there may be necrosis of syncytiotrophoblast. Fibrinoid necrosis is an acellular mass of dense eosinophilic material that often appears as a lump on the trophoblast basement membrane and is covered completely or partially by syncytiotrophoblast epithelium. As the mass expands, adjacent villi may become matted to the lesion. As a final process it is thought to replace the villous stroma. Clinically, both these processes are seen more frequently and more extensively in term or postterm placentas. Excess perivillous fibrin deposition may be seen in preterm placentas in association with severe intraamniotic infection. Intrauterine infection

may compromise the fetus in many ways besides the risks of sepsis. We have observed alterations in fetal heart rate, biophysical profile, and umbilical blood flow in association with intraamniotic infection. If infection leads to direct villous damage, nutrient transfer and gas exchange may be impaired.

Erythroblastosis and villous edema. In the adult 24 to 48 hours is required for the bone marrow to respond to hematopoietic stress by production of nucleated erythrocytes.[37] The presence of excess nucleated erythrocytes in placental circulation suggests a duration of stress for a minimum of 24 hours. We have observed excess nucleated erythrocytes only in the presence of placental histologic features that are more suggestive of chronic rather than acute insults. Intrauterine growth retardation and preeclampsia are examples of chronic processes that are often associated with excess production of nucleated erythrocytes.[38] In stillbirths the presence of nucleated erythrocytes suggests a more chronic stress and would speak against an acute intrapartum event as being the cause of the fetal damage.

An excess of nucleated erythrocytes in the placental circulation generally accompanies both immune and nonimmune hydrops, since both involve decreased tissue oxygen delivery and increased bone marrow activity. The excess release of immature nucleated erythrocytes from the marrow may be a response to accelerated erythrocyte destruction, as in Rh isoimmunization, or to bone marrow effects, as in congenital parvovirus infections.[39]

Erythroblastosis and villous edema are discussed together because they frequently coincide in diseases such as immune and nonimmune hydrops. In these situations the villous swelling mirrors the diffuse fetal edema. Fetoplacental edema has been associated with decreased red blood cell mass and decreased hepatic production of proteins leading to decreased intravascular oncotic pressure.[40]

Villous edema may be observed in several situations besides hydrops fetalis. Naeye et al.[41] reported the association of villous edema with acute intraamniotic infection. They suggested that villous swelling might result in decreased oxygen delivery to the fetus and fetal distress. We suggest that villous edema may be the result of inflammatory cytokines in the intervillous space, altering trophoblast and capillary permeability. It is possible that different bacteria may have different capacities to generate inflammatory cytokines and prostanoids (e.g., endotoxin-producing *Escherichia coli*). Further studies of the roles of inflammatory mediators in villous damage are necessary.

Acute and chronic fetal insults: The role of placental pathologic examination

The pathologist is trained to ask two questions: "Where is the lesion?" and "How long has it been there?" From the medicolegal point of view it is frequently assumed that the lesion was caused to a previously intact fetus during the course of labor and delivery. However, the fallacy of this reasoning is only beginning to become clear to the medical community. We must communicate this information to our patients. For better or worse the American society is one with high expectations, and a perfect baby is certainly among them. We value "fair play" and "justice." When the unexpected happens, American society looks for someone to be held accountable, because to have a damaged baby somehow "isn't fair." We certainly agree with this but suggest that the only way to prevent fetal and neonatal damage is to better understand the causes of such damage. Mann[42] has states that "At least half, if not more, of all brain-damaged children have no scientifically or clinically based explanation for their problem." Not more than 10% of severe mental retardation is considered to be attributable to perinatal causes.[43, 44]

Clearly, the search in the intrapartum period for the roots of every case of neurologic damage is not rewarding. This attitude toward the significance of intrapartum events and management stemmed in part from the belief that the intrauterine environment was the perfect nurturant environment for the duration of gestation, buffering the fetus from all hazards and stresses. Only on departure from this "nirvana" could the fetus be damaged. However, as the methods of antepartum fetal surveillance become more sensitive, it is becoming more evident that this is untrue. Bejar et al.[45] have described antepartum cerebral infarction linked to intraamniotic infection. It is recognized that clinical chorioamnionitis is a late stage in the process. The majority of cases of histologically evident intraamniotic infection, with umbilical vasculitis used as a marker, are clinically silent. Chasnoff et al.[35] linked maternal cocaine use to cerebral infarction. Their work[35] also suggests that cocaine use in early pregnancy may have lasting effects on the developing fetal central nervous system. In addition, we have observed the presence of placental thrombi in association with maternal cocaine use, which may possibly cause neurologic damage by acting as a source of thromboemboli. While it is recognized that congenital viral infection is associated with many forms of neurologic damage, most maternal infections are clinically silent. Therefore it is not surprising that in the overwhelming majority of cases of chronic villitis no antecedent maternal illness can be documented. These cases will be detected only where placental examination is routinely performed. It is a clinical truth that there are cases of preeclampsia in which maternal disease is severe and the fetus and placenta are normal and also cases of intrauterine fetal death associated with what clinically seems to be mild preeclampsia.

Robertson et al.[45a] have confirmed that the uterine

vascular anatomy of preeclampsia may occur in the absence of maternal signs and symptoms. We have also observed similarities in placental pathologic conditions between idiopathic intrauterine growth retardation and intrauterine growth retardation associated with preeclampsia. It may be that idiopathic intrauterine growth retardation is one form of preeclampsia that specifically targets the fetoplacental unit, sparing other maternal organ systems. We propose that processes linked to long-term compromise of neurologic function are usually clinically silent. These processes are more likely to be detected in routine gross and microscopic examination of the placenta.

The duration of fetal compromise is very important in regard to the likelihood of long-term neurologic damage. Myers' work[46] has shown that short exposure to complete asphyxia will most likely result in no long-term neurologic sequelae, while prolonged partial asphyxia will most frequently result in neurologic damage in a histologic distribution consistent with that observed in human cases of cerebral palsy. Clapp et al.[47] have shown cerebral damage and intermittent interference with the umbilical circulation. An understanding of the relative time-frame associated with the different placental processes is helpful. Acute ascending infection is generally a short-term process. In the presence of acute ascending infection the mother will go into labor soon or will become clinically infected, and the infant will be delivered. The life span of the adult polymorphonuclear leukocyte is approximately 2 to 3 days in tissue culture.[48] If fragmentation of polymorphonuclear leukocytes is present, one may suggest that the inflammatory event was initiated at least 2 days before delivery. Infiltrates with numerous or degenerating polymorphonuclear leukocytes will likely represent even longer durations and/or severity of inflammation. Trophoblast degenerative knots may develop as quickly as 24 hours after in vitro exposure to lowered oxygen tension. However, trophoblast knots are also common in situations of chronic uterine vascular insufficiency, such as preeclampsia. Trophoblast knots that develop as a response to an acute stimulus will be associated with normal-appearing villi. Trophoblast knots appearing as part of a more chronic process will have abnormal villous structure, including fibrosis and hypovascularity. Infarctions with loss of nuclear detail will likely be >7 days old. The "age" of chronic villitis may be a more complicated issue. The premature placenta, with its functionally immature macrophages, may be less capable of demonstrating a cellular infiltrate than a term placenta. Small foci of villitis in a preterm placenta may represent a significantly more severe and protracted inflammation than in a term placenta. We must also consider the possibility that inflammation may present in a different fashion in the very immature placenta. In the very immature placenta a cellular infiltrate may not develop. Instead, edema, a cardinal sign of inflammation, may be the only histologic evidence of inflammation. Therefore the gestational age of the placenta is critical to interpreting the presence of chronic inflammation.

Table III summarizes the approximate timing of the most common placental lesions. The relevance of these concerns to medicolegal issues is obvious. If a process capable of damaging the fetus can "more likely than not" be said to predate a patient's coming to the labor and delivery suite, the role of intrapartum obstetric care in the genesis of neurologic damage should be in serous doubt.

The need for placental pathologic examinations in all pregnancies

At present there is no cure for neurologic damage except the early detection of infants at risk for long-term compromise, permitting early intervention with remedial programs to optimize neurologic development. Examination of the placenta may provide the only source of evidence that such risk factors exist in a clinically "normal" pregnancy. Many investigations suggest that the consideration of placental lesions will provide information that is useful to both parents and pediatricians. Chronic villitis, for example, is associated with growth retardation in idiopathic preterm deliveries but not in preterm preeclampsia. Chronic villitis has been linked to congenital viral infection[26] but also has been suggested to reflect maternal-fetal immunopathologic conditions.[29, 30] We have observed a significant increase in chronic villitis among primiparous women, independent of other maternal factors (Salafia CM, Vintzileos AM, Silberman L. Placental pathology of idiopathic intrauterine growth retardation at term. To be published, 1990). The venous or arterial nature of placental thrombi, the presence or absence of intraamniotic infection, and all relevant clinical data must be considered together to assess the risk to the infant. Children and parents deserve better than a situation where "At least half if not more of children with neurologic damage have no scientifically or clinically based explanation for their problem."[42] Feelings of frustration and helplessness naturally accompany the loss of parents' dreams for their offspring when death or neurologic compromise of their child occurs. Parents will look for a "reason" for the unexpected bad outcome and, failing to find one, they will turn on themselves ("What did I do wrong?") or their care-givers ("What did my obstetrician do wrong?"). In many of these cases examination of the placenta is the only avenue to detect the clinically silent, and often untreatable, culprit. Table IV summarizes the possible causes of the most common placental lesions. Moreover, if the clinically

Table III. Approximate timing of placental lesions

Acute inflammation	Timing depends on depth of leukocyte migration (across membranes and chorionic plate) and severity of stimulus (type of organism and size of inoculum). May also vary with host response. If no degenerated leukocytes are present, stimulus likely to be present <48 hr. Presence and extent of leukocyte degeneration imply longer duration
Amnion nodosum	At least 1 wk of severe oligohydramnios
Meconium histiocytosis	At least 1 to 6 hr exposure to meconium. Deeper diffusion (into chorion) implies longer duration
Infarction	If no nuclear detail, at least 1 wk old. In lesions with nuclear detail (<1 wk old) degree of trophoblast and stromal preservation implies a greater or lesser age
Abruptio placentae	Dated by adjacent villous changes (see Infarction above)
Intervillous thrombosis	Age varies with maternal and fetal blood types, volume of clot, and regional flow characteristics
Chronic villitis	Days to months
Placental intravascular thrombi	Days to months
Maternal floor infarction	Weeks to months

Table IV. Possible causes of placental lesions

Acute inflammation	Acute ascending chorion-decidua, amnion, infection of vaginal chorionic plate, chorionic vessel; organisms such as umbilical cord bacteria, yeast, mycoplasma (rarely the result of hematogenous spread of maternal sepsis, e.g., listeriosis, streptococcus)
Infarction, intervillous thrombosis	Decidual vasculopathy (related to preeclampsia or preexisting maternal medical disease), maternal cocaine use, May occur near margins of normal placentas
Abruptio placentae	Decidual vasculopathy (related to preeclampsia or preexisting maternal medical disease), maternal cocaine use. More frequent in acute inflammation
Maternal floor infarction	? Maternal-fetal immunopathologic condition, may be recurrent
Chronic villitis	Congenital infection (e.g., TORCH). Maternal-fetal immunopathologic condition, especially with history of recurrent poor pregnancy outcome
Hemorrhagic endovasculitis	Circulatory instability (e.g., preeclampsia, stillbirth). Often associated with other placental lesions (e.g., infarction, thrombosis, chronic villitis)
Erythroblastosis and edema	Immune and "nonimmune" hydrops, congenital viral infection, acute inflammation. Erythroblastosis may be seen in intrauterine growth retardation, preeclampsia, or antiphospholipid antibody disease with massive placental infarction
Placental intravascular thrombi	Associated with other placental lesions (infarction, chronic villitis hemorrhagic endovasculitis). Possible association with maternal cocaine use
Meconium histiocytosis	Significance varies with gestational age. At term may be insignificant. May be seen with fetal distress
Amnion nodosum	Chronic decrease in amniotic fluid volume

silent problem detected by placental examination is treatable, subsequent pregnancy outcome may be improved. On the basis of placental gross and/or microscopic findings, we have suggested that there are certain conditions that are well treatable but all have a high risk of recurrent poor outcome if not treated. These conditions include abnormal immunity to group B streptococcus, presence of maternal antiphospholipid antibody, lack of antipaternal blocking factors, and decidual vasculitis with positive antinuclear antibodies in the absence of clinical lupus erythematosus. Several of these patients have subsequently had their first uncomplicated pregnancy after treatment and appropriate surveillance. Since most long-term neurologic compromise will not be detectable until after 1 year of age, routine examination of all placentas would appear to be the only way to consistently provide these vital data.

Cost-effectiveness of routine placental pathologic examination

Defense lawyers and insurance companies have recognized the potential value of placental examination in medicolegal cases. Some investigators have suggested that sections from all placentas should be saved or that

paraffin blocks be prepared but slides not be cut or examined until the information is needed. We feel that this is a failure to see the broad implications of placental pathologic examination. Space in most hospitals is at a premium, and significant space is required to store placentas or even placental blocks. How long should a placenta be saved? A healthy infant at birth or at hospital discharge at 3 days of age does not guarantee a healthy, intact child. Many forms of neurologic compromise resulting from antepartum fetal insults may not manifest themselves until months after birth.

In many states that average award for medical negligence in cases of cerebral palsy is $5 to $6 million and the average settlement award is $1.5 million. The costs of placental examination in Connecticut average $225. The busy obstetricians delivers approximately 300 infants a year. Over 30 years of practice, he/she will deliver approximately 9000 infants. The total cost generated by routine examination of all these placentas would be approximately $2 million. This generated cost is much less than the average award for medical malpractice of $5 to $6 million and worthwhile to avoid one case of alleged medical malpractice. We feel that placental examination should occur at delivery and not after problems arise in the early years of life. We therefore suggest that routine examination of the placenta should be as much a part of normal care in pregnancy as the assignment of Apgar scores.

Comment

In cases of poor neonatal outcome, examination of the placenta may not only identify the exact cause but also give an indication of the time-frame characteristics of the insult. This information will lead to clearer understanding of the origin of the abnormal neurologic outcome (e.g., infectious or decidual vascular) and also to appropriate determination of medicolegal responsibilities for the poor outcome. The benefits of placental examination in cases of poor neonatal outcome are well recognized in the literature.

It is our opinion that the significant benefits of routine placental examination for all deliveries have not been recognized. Routine placental examination is the only tool that we can possibly use to better understand causes of intrauterine neurologic insult. Without this understanding we cannot develop methods to prevent or treat those clinically silent intrauterine processes. It is time that the medical community starts thinking about effective screening methods to permit early identification of the 80% of neurologically damaged children who have no history of peripartum distress. At the same time this approach will figure prominently in medicolegal defense.

Role of vasopressin in mediation of fetal cardiovascular responses to acute hypoxia

Kathleen M. Piacquadio, MD, Robert A. Brace, PhD, and Cecilia Y. Cheung, PhD
La Jolla, California

The present study was designed to test the hypothesis that arginine vasopressin mediates the fetal cardiovascular response to acute hypoxia. Chronically catheterized sheep fetuses at 126 to 138 days' gestation were infused with either an arginine vasopressin pressor antagonist (n = 8) or saline solution as control (n = 8). A 30-minute hypoxia was induced by infusion of nitrogen containing 5% carbon dioxide into the maternal trachea. Fetal arterial Po_2 decreased 13.1 ± 1.3 (SE) mm Hg from a basal value of 23.8 ± 1.5 mm Hg and there was no significant difference in the degree of hypoxia between the two groups. Fetal arterial and venous pressures increased significantly, whereas the blood volume decreased, but these changes were similar between the control and arginine vasopressin–blocked fetuses. Heart rate fell similarly in both groups during hypoxia by an average of 35 beats/min. At the termination of hypoxia, heart rate in the blocked group rebounded to levels significantly above baseline and remained elevated for 30 minutes, whereas heart rate in the control group returned slowly to basal values. Recovery of arterial pressure, venous pressure, and blood volume were similar in the two groups. Thus it appears that arginine vasopressin may mediate in part the fetal heart rate response to acute hypoxia. However, the blood volume, arterial pressure, and venous pressure responses to hypoxia appear to be induced by factors other than arginine vasopressin. (Am J Obstet Gynecol 1990;163:1294-300.)

Key words: Fetus, heart rate, arterial pressure, venous pressure, blood volume, arginine vasopressin

Moderate to severe acute hypoxia in the ovine fetus is associated with increases in arterial and venous pressures but decreases in heart rate and blood volume.[1-4] These cardiovascular changes have been shown to be mediated at least in part by circulating catecholamines.[2, 5-9] However, after α-adrenergic plus β-adrenergic receptor blockade in the fetal sheep, the rise in vascular pressures during hypoxia is attenuated and delayed but not abolished,[10] suggesting that in addition to the catecholamines other factors may be responsible for the mediation of the cardiovascular changes in response to hypoxia. In view of the fact that large increases in fetal plasma arginine vasopressin concentrations occur during severe hypoxia[4, 11] and that arginine vasopressin is a potent vasoconstrictor that, when infused into the fetus, produced arterial and venous hypertension and bradycardia,[12-14] it is possible that arginine vasopressin may mediate some of the cardiovascular responses to hypoxia in the fetus. Previously we reported that in association with the hypertension and bradycardia, fetal blood volume decreases during both mild and severe hypoxia.[10] This fall in blood volume during mild hypoxia is mediated by the catecholamines. However, during severe hypoxia the blood volume changes can no longer be reversed by α-adrenergic plus β-adrenergic receptor blockade. Because fetal plasma arginine vasopressin levels increase during acute hypoxia when Po_2 falls below 17 mm Hg,[15, 16] arginine vasopressin could play a role in mediating the decrease in fetal blood volume during severe hypoxia. The present study was designed to test the hypothesis that the arterial and venous hypertension and bradycardia that occur during acute severe hypoxia are mediated by arginine vasopressin. In addition, the possibility that arginine vasopressin may induce the fetal blood volume response to severe hypoxia was investigated. For these studies, the fetal cardiovascular V_1 receptors were blocked by the use of the pressor antagonist $d(CH_2)_5-Tyr(Me)$ arginine vasopressin. (Peninsula Laboratories, Belmont, Calif.)

Methods

Animal preparations. Eleven time-dated pregnant ewes with singleton fetuses at an average gestational age of 131 ± 1 (SE) days (Nebeker Ranch, Lancaster, Calif.) were used for the study. After anesthesia was induced with administration of halothane to the ewe, catheters were placed in the fetal tibial arteries and saphenous veins, and the tips were advanced to the level of the diaphragm to rest in the descending aorta and inferior vena cava, respectively.[17] Two additional catheters were placed in the amniotic cavity. An indwelling catheter was placed in the maternal femoral vein. All catheters were tunneled subcutaneously to a nylon pouch sewn to the flank of the ewe. A nonocclusive catheter was placed in the maternal trachea through a small midline incision in the neck.[18] Prophylactic antibiotics, consisting of 800,000 U penicillin G plus dihydrostreptomycin, Pfizer, New York) intramuscularly to the ewe and 1 gm ampicillin (Omnipen, Wyeth Laboratories, Inc., Philadelphia) into the amniotic fluid, were administered on the first 5 postoperative days and after each experimental session. Vascular catheters were flushed daily with heparin sodium solution (1000 U/ml).

Experimental protocol and measurements. The first experiments were conducted at least 5 days after surgery when the gestational age of the fetuses was 132 ± 1 (SE) days. In five animals, a second experiment was performed 2 days after the first. The animals subjected to two experiments were randomly assigned to either the arginine vasopressin antagonist or control group for their first experiment and to the opposite group for their second experiment. The experimental protocol consisted of a 30-minute control period and a 30-minute period of hypoxia, followed by a 3-hour recovery period. Hypoxia was induced by the infusion of nitrogen containing 5% carbon dioxide into the trachea of the ewe while the ewe was freely breathing room air. In fetuses subjected to arginine vasopressin blockade, the pressor antagonist $d(CH_2)_5$ −Tyr(Me) arginine vasopressin was administered intravenously as a 25 μg bolus in 3 ml 0.9% sodium chloride at the start of the experiment. This was followed by a continuous infusion of the arginine vasopressin analog at 1 μg/min (in 0.39 ml/min of isotonic saline solution) for the duration of the experiment. Control fetuses received a 3 ml bolus of 0.9% sodium chloride followed by a continuous infusion of 0.9% sodium chloride at a similar rate. Preliminary studies were performed to ensure the effectiveness of blockade for the pressor effects of arginine vasopressin. With the same dose of the arginine vasopressin antagonist as in the present study, the increase in fetal arterial pressure in response to an intravenous 30 ng bolus of arginine vasopressin was abolished. On the other hand, when given alone the antagonist had no effect on arterial or venous pressures or heart rate.

Fetal arterial pressure, venous pressure, heart rate, and amniotic fluid pressure were continuously monitored on a polygraph recorder and mean values were stored at 30-second intervals with an on-line computer as previously described.[17] Amniotic fluid pressure was used as the zero pressure reference for fetal vascular pressures. Fetal arterial blood (4 ml) was sampled at 15-minute intervals for the first 2 hours of the experiment and at 1 hour intervals for the last 2 hours. The volume of each blood sample removed was replaced with an equivalent amount of maternal blood to prevent a sampling-induced decrease in hematocrit. Three milliliters of blood was placed in each chilled heparinized tube containing aprotinin (Trasylol, Sigma Chemical, St. Louis, Mo.) at 500 KIU/ml and then centrifuged. The plasma was stored at −70° C until used for hormone concentration measurements. One milliliter of blood was used to measure blood gas and pH values (IL1302 blood gas analyzer at 39.5° C) as well as microhematocrit in triplicate as previously described.[19, 20] Blood volume as a fraction of that before the hypoxia was calculated as the mean hematocrit during the prehypoxic period divided by the hematocrit of each sample. This method has been shown to be valid.[19, 20] In addition, because the hematocrit values during the control period in the control and arginine vasopressin–blocked fetuses were similar (Table I), arginine vasopressin did not appear to have significant effects on hematocrit measurements.

Radioimmunoassay. Plasma arginine vasopressin concentrations were determined by a double antibody radioimmunoassay procedure with antiserum generously provided by Dr. Benjamin U (University of California, San Diego, Calif.). The plasma samples were extracted with C18 microcolumns (Sep Pak, Waters Associates, Milford, Mass.) as described previously.[21] The extraction efficiency as determined by the addition of 50 pg arginine vasopressin standard to 1 ml of plasma was 92.4% ± 4.7%. The intraassay and interassay coefficients of variation for the assay were 5.6% and 16.0%, respectively. The minimum amount of arginine vasopressin detectable was 0.2 pg per tube. Arginine vasopressin measurements were not performed in the fetuses that received the antagonist because this compound cross-reacted 100% with the arginine vasopressin antiserum.

Data analysis. The data are expressed as the mean ± SE. A p value of <0.05 was considered statistically significant. Potential differences in mean values in the control and antagonist-treated fetuses during the control period before hypoxia were analyzed with an unpaired Student t test. To determine whether there were

Table I. Control cardiovascular and arterial blood gas variables in ovine fetuses at 126 to 133 days' gestation

Variable	*Controls**	*Arginine vasopressin blocked**
Arterial pressure (mm Hg)	45.7 ± 2.2	44.3 ± 2.9
Venous pressure (mm Hg)	4.2 ± 0.2	4.1 ± 0.6
Heart rate (beats/min)	175 ± 4	167 ± 8
Oxygen tension (mm Hg)	21.4 ± 1.2	24.5 ± 1.3
Carbon dioxide tension (mm Hg)	53.2 ± 1.8	53.9 ± 1.5
pH	7.33 ± 0.01	7.32 ± 0.02
Hematocrit (%)	33.4 ± 2.9	30.9 ± 1.5
Plasma arginine vasopressin (pg/ml)	4.8 ± 0.8	†

Values are presented as mean ± SE.
*$N = 8$.
†Arginine vasopressin concentrations were not measured in this group.

statistically significant changes with time in one variable, a two-way analysis of variance for repeated measurements was used. To determine whether the changes with time in the control group were different from those in the arginine vasopressin–blocked group, a two-way analysis of variance for replication and repeated measurements was used. The relationship between two variables at a given time was analyzed with bivariate regression analysis methods.

Results

In ovine fetuses at 126 to 133 days' gestation, mean vascular pressures, heart rate, blood gas values, and plasma arginine vasopressin concentration during the 30-minute control period in the groups treated with arginine vasopressin antagonist and saline solution are shown in Table I. There were no significant differences in these variables between the two groups. These values are consistent with those obtained in our laboratory.

The changes in fetal arterial blood gas and pH values during hypoxia in the arginine vasopressin–blocked and control fetuses are shown in Fig. 1. In the control fetuses, P_{O_2} decreased by 9.9 ± 1.4 mm Hg to 11.5 ± 0.8 mm Hg in response to hypoxia, whereas in the arginine vasopressin–blocked fetuses, the P_{O_2} fell by 12.8 ± 1.2 mm Hg to 11.8 ± 0.8 mm Hg. Arterial P_{O_2} returned to basal levels immediately after the termination of hypoxia. There was no significant difference in the degree of hypoxia achieved in the two groups. During hypoxia the fetal arterial pH and P_{CO_2} changes were similar in the two groups (Fig. 1); arterial pH did not change, whereas P_{CO_2} fell significantly. Immediately after the hypoxic episode, pH decreased, whereas P_{CO_2} increased significantly but returned to baseline within 60 minutes.

The changes in arterial pressure, venous pressure, and heart rate during hypoxia in the control and arginine vasopressin–blocked fetuses are shown in Fig. 2. Arterial pressure increased during hypoxia ($p < 0.0001$) in the fetuses treated with saline solution, and these changes were not significantly altered by the arginine vasopressin blockade. In both groups, arterial pressure decreased immediately after the hypoxia, followed by a secondary rise to levels above the control, and returned to baseline by the second hour of the recovery period. Venous pressure increased during hypoxia ($p < 0.0001$) and immediately returned to basal levels after hypoxia. The venous pressure responses were not different in the two groups.

During hypoxia, heart rate fell similarly in both groups of fetuses by an average of 35 beats/min ($p < 0.0001$). In the immediate posthypoxic period, heart rate in the arginine vasopressin–blocked fetuses rapidly increased to levels significantly higher than baseline. Heart rate in the control fetuses remained depressed and gradually returned to basal levels at 30 minutes after hypoxia. These changes in fetal heart rate during the recovery period were different between the two groups ($p < 0.01$).

Fetal blood volume during hypoxia decreased by 8.0% ± 1.0% and 10.8% ± 1.3% in the control and arginine vasopressin–blocked groups, respectively (Fig. 3). There was no significant difference in the fall in blood volume between the two groups. With bivariate regression analysis, a significant ($p < 0.006$) linear relationship was found between the decrease in blood volume and the fall in P_{O_2} in the two groups at the end of hypoxia (Fig. 4).

Fig. 5 shows the increase in plasma arginine vasopressin concentrations in control fetuses during and after the hypoxic period. Plasma arginine vasopressin concentrations increased from a mean basal value of 4.8 ± 0.8 pg/ml to 60.6 ± 27.1 pg/ml at the end of the 30-minute hypoxic period ($p < 0.001$). Arginine vasopressin levels gradually returned to baseline within 30 minutes after the end of hypoxia.

Fetal arterial blood gas tension and pH changes (mean ± SE) during control, hypoxic, and recovery periods in controls *(open circles)* and arginine vasopressin–blocked *(closed circles)* ovine fetuses. Data are expressed as change from mean control value during the first 30 minutes. *Vertical dotted lines* indicate beginning and end of hypoxia.

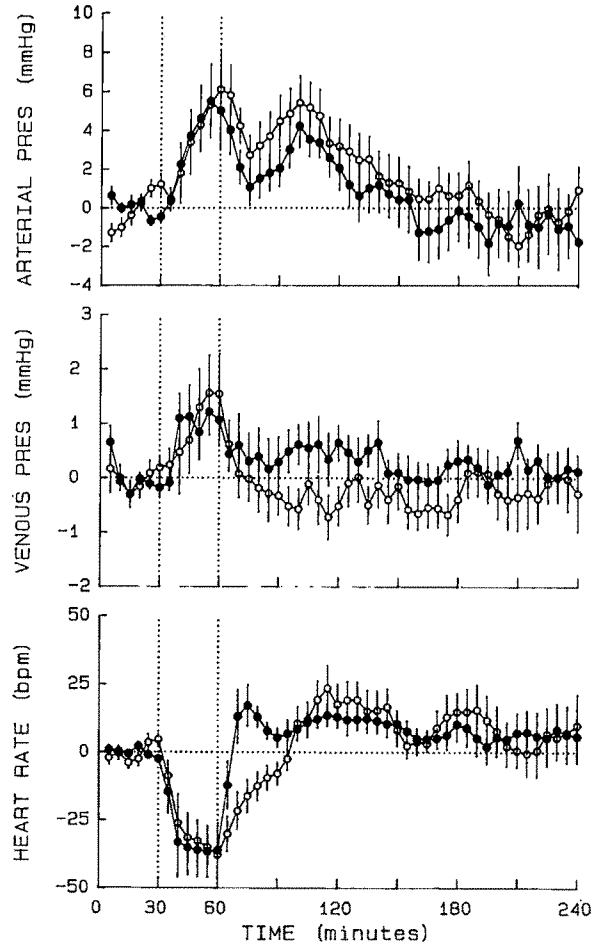

Fig. 2. Changes in fetal arterial pressure, venous pressure, and heart rate (mean ± SE) during control, hypoxic, and recovery periods in control *(open circles)* and arginine vasopressin–blocked *(closed circles)* fetuses. Data are expressed as change from mean control value during the first 30 minutes. *Vertical dotted lines* represent beginning and end of hypoxia.

Comment

Previous studies showed that moderate to severe hypoxia is a potent stimulus for release of arginine vasopressin into the fetal circulation and cerebrospinal fluid.[4, 11] In addition, intravenous infusions of exogenous arginine vasopressin into the ovine fetus increase arterial and venous pressures and decrease heart rate and blood volume.[4, 12-14] These cardiovascular responses to exogenous arginine vasopressin are all directionally consistent with those induced by fetal hypoxia. In addition, the increases in arterial and venous pressures and decreases in heart rate and blood volume during hypoxia coincide with the rise in plasma arginine vasopressin concentration.[4] Thus it was reasonable to hypothesize that, in the fetus, arginine vasopressin was responsible in part for the rise in arterial and venous pressures and decrease in heart rate and blood volume that occur in response to hypoxia. However, we found that blockade of the pressor effects of arginine vasopressin did not significantly alter the increases in arterial and venous pressures during hypoxia. Thus it appears that factors other than arginine vasopressin are responsible for the vascular pressure changes during acute hypoxia in the fetus. Our findings appear to contrast with a recent report of Perez et al.[22] who found that the hypertension during hypoxia in the sheep fetus was partially reversed when the same arginine vasopressin antagnoist as that used in our study was administered at the midpoint of the hypoxic period. However, although no statistical analyses were performed, it can be seen in the data of Perez et al.[22] that, even though the blocker lowered arterial pressure when administered during hypoxia, at no time was arterial pres-

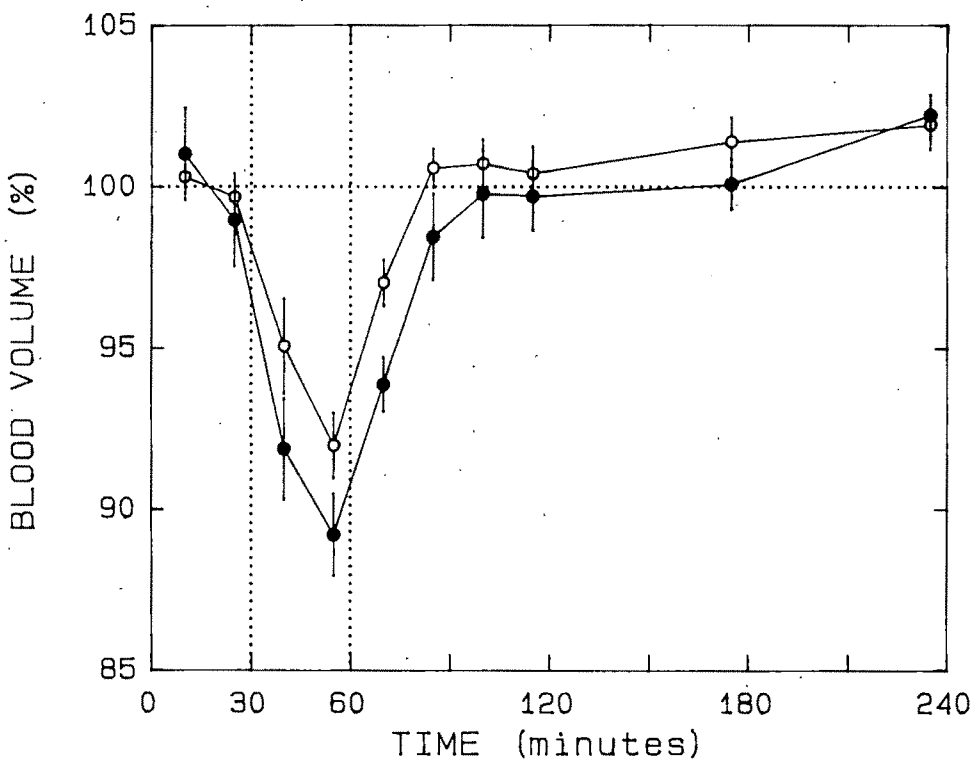

Fig. 3. Changes in blood volume (mean ± SE) during severe hypoxia in control *(open circles)* and arginine vasopressin–blocked *(closed circles)* fetuses. Data are expressed as percentage of mean control during the first 30 minutes. *Dotted vertical lines* represent beginning and end of hypoxia.

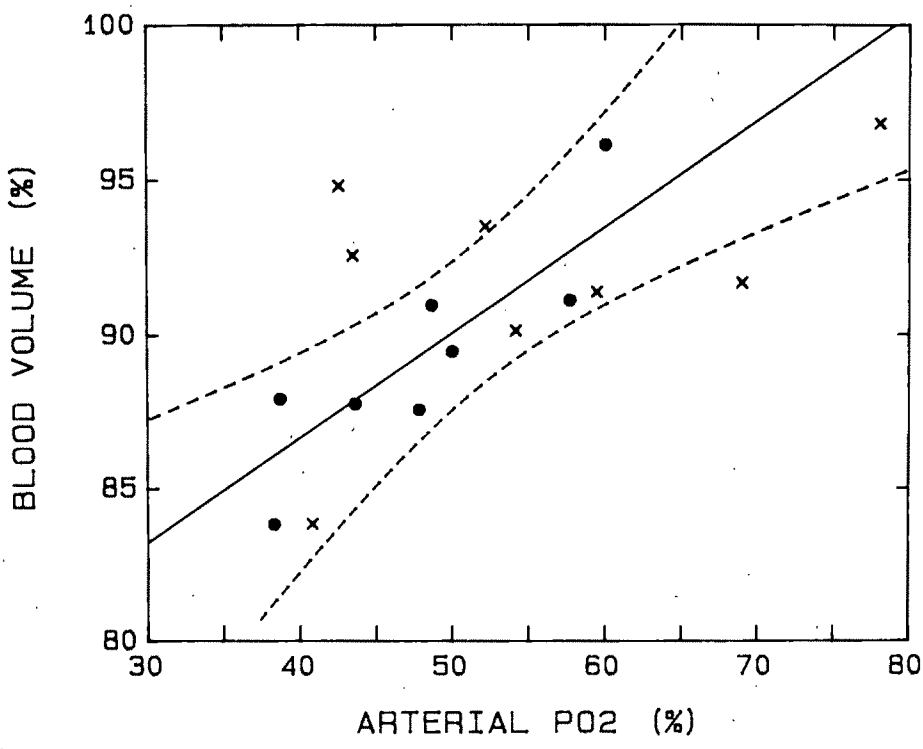

Fig. 4. Correlation between changes in arterial Po_2 and blood volume in control *(crosses)* and arginine vasopressin–blocked *(closed circles)* ovine fetuses at end of hypoxic period ($r = 0.653$, $p < 0.01$).

sure in the blocked fetuses significantly different from that in the control fetuses. Thus the contribution of arginine vasopressin to the fetal arterial hypertension during acute hypoxemia is subtle and difficult to detect if it does indeed occur. Alternatively, it is possible that under the situation when the arginine vasopressin system is blocked during hypoxia, other pressor systems are activated to compensate for the lack of arginine vasopressin effects in the restoration of cardiovascular function to normal.

In addition to the arterial hypertension, an important component of the fetal cardiovascular response to acute severe hypoxia is venous hypertension. This study confirms our previous observation[10] of an elevation in venous pressure during hypoxia. Furthermore, this study shows that even if an arginine vasopressin blocker were present before the onset of hypoxia, the venous pressure response to hypoxia was not altered. Thus arginine vasopressin does not appear to be a primary mediator of the hypoxia-induced venous hypertension in the late gestation ovine fetus, even though exogenous arginine vasopressin at high doses elevates fetal venous pressure.[12]

We and others[4, 12-14] have shown that infusion of arginine vasopressin into the ovine fetus results in bradycardia. We speculated that the decrease in heart rate during hypoxia could be partially mediated by arginine vasopressin. However, because the decrease in heart rate during hypoxia was similar in both the control and arginine vasopressin–blocked fetuses, it appears that arginine vasopressin does not mediate the fetal heart rate changes during hypoxia. Subsequent to hypoxia we observed a tachycardia at the beginning of the recovery period in fetuses treated with the antagonist, whereas heart rate remained suppressed in control fetuses at this time. Inasmuch as the arterial and venous pressure responses at this time were similar between the two groups, these findings suggest that fetal heart rate in the immediate posthypoxic period may be modulated by a direct action of arginine vasopressin on heart rate, and this action is sensitive to blockade by the pressor antagonist. Alternatively, arginine vasopressin may alter fetal heart rate indirectly through interaction with other endocrine factors such as the catecholamines. Conclusions similar to ours were obtained from the study by Perez et al.[22] in which the fall in fetal heart rate during hypoxia was partially reversed by the arginine vasopressin antagonist. This conclusion is further supported by the present observation that the return of heart rate to basal levels in the control fetuses paralleled the return of plasma arginine vasopressin to basal concentrations.

Hypoxia induced a decrease in fetal blood volume that most likely results from an increase in capillary pressure.[10] We have previously demonstrated that the catecholamines may mediate this fall in blood volume only when the degree of hypoxia is mild.[10] With moderate to severe hypoxia (fall in Pa_{O_2} of >6 mm Hg), the blood volume changes can no longer be accounted for by the catecholamines, because combined α-adrenergic plus β-adrenergic receptor blockade does not alter the blood volume decrease during severe hypoxia.[10] It has been suggested that acidosis may contribute to the decrease in blood volume during hypoxia,[23] but the fall in blood volume precedes the decrease in blood pH.[10] Because infusion of arginine vasopressin into the ovine fetus decreases blood volume[12] and plasma arginine vasopressin concentrations increase during hypoxia when fetal Pa_{O_2} falls below 17 mm Hg,[15, 16] it was reasonable to speculate that the fall in fetal blood volume during severe hypoxia may be attributable to the rise in plasma arginine vasopressin concentrations. However, in the present study the fall in fetal blood volume was similar between the control and arginine vasopressin antagonist—treated groups, thus eliminating the possibility that arginine vasopressin might mediate this change in blood volume. In support of this finding was the fact that the increase in venous pressure in these fetuses was not altered by treatment with arginine vasopressin antagonist. In other words, with similar increases in venous and arterial pressures, it is not surprising to find similar changes in blood volume because the changes in capillary pressure are most likely similar.

In summary, circulating arginine vasopressin in the ovine fetus does not appear to mediate the arterial or venous hypertension or the hypovolemia induced during acute hypoxia. However, arginine vasopressin appears to mediate part of the posthypoxic bradycardia that occurs in these fetuses.

Autologous antibodies eluted from membrane fragments in human ovarian epithelial neoplastic effusions

III. Cytotoxic potential in vitro and characterization of antigen(s)

William H. Kutteh, MD, PhD,[a] Vicki V. Baker, MD,[a] and George J. Doellgast, PhD[b]
Birmingham, Alabama, and Winston-Salem, North Carolina

Cyst and ascites fluids from patients with ovarian epithelial neoplasms contain immunoglobulins with antitumor activity. Autologous antibodies bound to the cellular membrane fragments obtained from human ovarian neoplastic effusions react with cell-surface antigens on different human ovarian cell lines, surgical specimens of human ovarian adenocarcinoma, and human ovarian tumors grown in athymic Balb/c mice. The antibodies do not react with tissue preparations from normal human ovaries, other nonovarian normal or neoplastic tissues, and nonovarian human cell lines. These studies indicate that these antibodies are capable of complement-mediated lysis of human ovarian tumor cell lines in vitro. Preliminary characterization of the autologous ovarian tumor-associated antigen(s) indicates that it may be composed of three large-molecular-weight proteins of 182,000, 164,000, and 122,000 d. (AM J OBSTET GYNECOL 1990;163:1301-6).

Key words: Ovarian cancer, tumor-associated antigens, tumor immunology, autologous antibodies

Ovarian carcinoma is the fifth leading cause of cancer death in women and the leading cause of death from gynecologic malignancies. More than 12,000 women die annually from this type of cancer.[1] Despite extensive use of operation, radiotherapy, and chemotherapy, the age-adjusted cancer death rate for cancer of the ovary has demonstrated a gradual increase from four deaths per 100,000 female population in 1930 to the present rate of 10 deaths per 100,000 female population.[1] The deep location of the organ and the lack of early symptoms make the diagnosis of ovarian cancer difficult; two thirds of the cases are not diagnosed until regional or distant metastases have occurred.[2] The most effective therapeutic courses against cancer of the ovary can provide only palliation with uncertain prolongation of life.

The most effective means of increasing survival rate is through early diagnosis of patients with ovarian cancer; thus many research efforts are currently under way to devise such detection methods. The majority of these efforts focus on the identification of tumor-associated or tumor-specific antigens as demonstrated by Gall et al.[3] Cells undergo changes that often result in the expression of new or altered cell products and cell-surface components as a consequence of transformation to the neoplastic state. Current evidence suggests that several classes of tumor-associated substances exist: those that are unique to a given tumor, those that are common to all tumors of a given histopathologic type, those that are associated with a given organ or tissue, those that may represent embryonic or transplantation-like antigens, as well as those that are ubiquitous in normal allogenic and xenogeneic cells.[4, 5]

The autologous antibodies isolated from human ovarian membrane fragments in this laboratory have a high degree of specificity for ovarian tumors but do not bind to normal ovarian or nonovarian tissues, or to nonovarian neoplastic tissues. These antibodies differ significantly from those described by other investigators who have produced heterologous polyclonal and monoclonal antibodies to ovarian tumor antigens such as OTA,[3] OVC,[6] IOTA,[7] OvTAA,[8] OCA,[9] OCAA and others,[10] NB-70K,[11] and OC 125.[12] This laboratory has demonstrated that patients with ovarian neoplasms are capable of initiating a specific immune response characterized by antibodies that recognize autologous ovarian tumor-associated antigen(s).[13-15] In this study, human ovarian tumor cell lines have been used as a source for the characterization of cell-surface antigens

reactive with membrane-eluted antibodies. These studies extend our previous reports by demonstrating that autologous antibodies eluted from membrane fragments of human ovarian neoplasms are capable of cytotoxicity against human ovarian cancer cell lines in vitro.

Material and methods

Preparation of membrane eluted antibodies. The detailed methods for preparation, purification, and specificity testing of ovarian membrane-eluted antibodies have been described.[14, 15]

Tissues and cells. Human use approval was granted through the Institutional Review Board for the collection and use of human tissue. Effusions from human ovarian epithelial neoplasms (T.E.B., J.B.S., E.M.D., and V.I.F.) and pleural fluid from a patient with Crohn's disease (W.M.J.) were obtained from the Pathology Services at the Bowman Gray School of Medicine (Table I). Human cell line No. 2774, derived from an ovarian serous cystadenocarcinoma, was provided by Phillip DiSaia, MD (University of California, Irvine, Orange, Calif.). Cell line No. 7315, also derived from an ovarian serous cystadenocarcinoma, was established at Bowman Gray School of Medicine.[14] Normal human tissues were obtained from the Tissue Procurement Service, Comprehensive Cancer Center (University of Alabama at Birmingham, Birmingham, Ala.). Human cell lines were maintained in culture in RPMI 1640 (Gibco, Grand Island, N.Y.) supplemented with 10% fetal calf serum, penicillin (0.1 mg/ml), streptomycin (100 U/ml), and 2.0 mmol/L L-glutamine (Gibco) at 37° C in an atmosphere of 95% air and 5% oxygen. Peripheral blood lymphocytes used as control cells in the cytotoxicity assay (described below) were prepared from whole blood.[16]

Immunofluorescence. Two preparations of autologous ovarian membrane-eluted antibodies (T.E.B. and J.B.S.) were tested against a panel of human tumor cell lines, fresh human tumor tissue, and fresh normal human tissue by indirect immunofluorescence. Names of each cell line and tissue tested have been previously listed.[14] Adherent cells were removed from tissue culture flasks with 0.25% trypsin for 5 minutes, washed three times in phosphate-buffered saline solution that contained 1% bovine serum albumin and 0.03% sodium azide, and adjusted to a concentration of 1×10^7 cells/ml. Equal volumes of membrane-eluted antibodies, immunoglobulin G (IgG) from normal serum, or buffered saline solution were incubated with washed cells for 45 minutes at 22° C. Cells were washed twice and then incubated with the fluorescein-labeled antihuman IgG, IgM, and IgA (heavy-chain-specific) (Calbiochem-Behring, Davis, Calif.). After 45 minutes at 22° C the cells were washed twice, resuspended in buffer, mounted on a slide, and examined immediately. Tissue sections embedded in 7.5% buffered gelatin were frozen, cut, mounted, and then stained by means of similar techniques. Cells and tissue sections were visualized by means of an Olympus BH-2 microscope (Olympus Optical Co., Ltd., Tokyo) with epiillumination.

Immunoglobulins. Normal human IgG was used as one control source of antibody for immunofluorescence and in the cellular cytotoxicity assay. The methods used for the preparation of IgG from the sera of normal individuals have been described previously.[16]

Cytotoxicity assay. To determine whether purified autologous antibodies from patients with ovarian cancer were capable of cellular killing against human ovarian tumor cells in vitro, we used a complement-mediated cellular cytotoxicity assay.[17] Briefly, single-cell suspensions of ovarian tumor cells or control cells were prepared as described above and washed three times. Cells (5×10^4) were incubated with serial twofold dilutions of membrane-eluted antibodies or control immunoglobulin (10 μl) for 30 minutes at 37° C in 96-well U-bottom microplates (Costar, Cambridge, Mass.). Guinea pig serum was added as a source of complement (Pel-Freeze Biologicals, Rogers, Ark.) (10 μl) and cells were further incubated for 30 minutes at 37° C. The reaction was stopped with cold 0.015 mol/L ethylenediaminetetraacetic acid (Sigma, St. Louis) and then 10 μl of 0.4% trypan blue (Gibco) was added to each well to evaluate viability by the dye exclusion assay. The percent of cells taking up dye per total number of cells present was determined by light microscopy and is reported as percent killing. Each dilution was performed in triplicate with mean values reported. Similar results were obtained with ovarian tumor cells when single cell

Table II. Immunofluorescence specificity of autologous membrane antibodies

Source of cells	*Type of cells*	*No. positive/No. tested*
Human tumor cell lines	Ovarian adenocarcinoma	8/8
	Colon adenocarcinoma	0/6*
	Uterine carcinoma	0/4
	Breast adenocarcinoma	0/2
Neoplastic human tissues	Ovarian adenocarcinoma	8/8
	Colon adenocarcinoma	0/4*
	Uterine carcinoma	0/4*

	Lung	0/2

*Trace immunofluorescence was observed in one colon adenocarcinoma cell line, and one sample each of neoplastic tissue obtained from a colon adenocarcinoma and a uterine carcinoma. (Table modified and updated from Kutteh WH, Welander CE, Homesley HD, Doellgast GJ. AM J OBSTET GYNECOL 1985;153:124-9.)

suspensions were obtained by either mechanical disruption or treatment with 1 mmol/L ethylenediaminetetraacetic acid.

Characterization of tumor-associated antigen(s). Cells from the human serous cystadenocarcinoma line No. 2774 (or No. 7315) were surface labeled with iodine 125–sodium by the lactoperoxidase method, cells were washed, and then membrane antigens solubilized with Triton X-100 (United States Biochemical Corp., Cleveland). Labeled antigens were precipitated with autologous ovarian membrane-eluted antibodies (T.E.B., J.B.S., E.M.D., or V.I.F.) or controls (W.M.J., normal IgG, or phosphate-buffered saline solution) and immune complexes were precipitated with goat antihuman IgG. The precipitates were washed to remove excess radioactivity, reduced with β-mercaptoethanol, and electrophoresed on 7.5% reducing polyacrylamide gels. Gels were sliced into 1 mm sections, slices were counted for radioactivity, and counts per minute per slice were plotted based on relative mobility of molecular weight standards.[18]

Results

Specificity of membrane-eluted immunoglobulins. To determine whether these membrane-bound immunoglobulins demonstrated any activity against ovarian tumors, immunoglobulins were eluted from membrane fragments, and their binding activity to various normal and neoplastic tissues was investigated. The autologous membrane-eluted antibodies reacted strongly

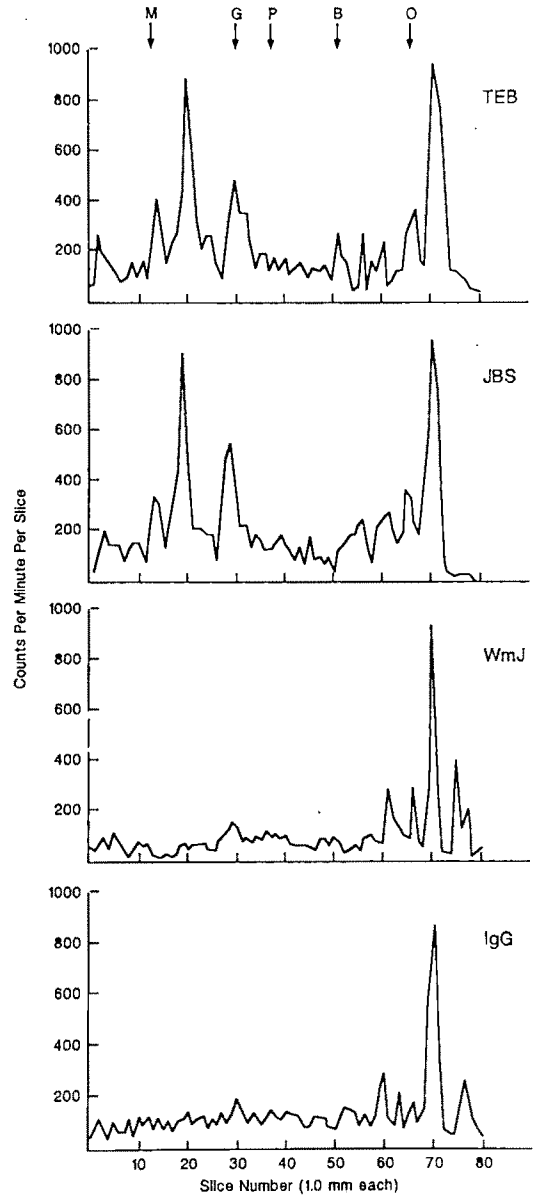

Fig. 1. Molecular weight characterization of autologous ovarian tumor-associated antigen. Human ovarian cystadenocarcinoma cell line No. 2774 was surface labeled with ^{125}I-sodium; cells were washed then solubilized with Triton X-100. Solubilized material was precipitated with autologous ovarian membrane-eluted antibody (T.E.B. or J.B.S.) or control immunoglobulin (W.M.J. or normal IgG); precipitates were washed and electrophoresed on 7.5% reducing polyacrylamide gels. Graphs depict counts per minute per 1 mm slice compared with relative mobility of molecular weight standards (*M*, myosin, 205,000 d; *G*, β-galactosidase, 116,000 d; *P*, phosphorylase B, 97,500 d; *B*, bovine serum albumin, 67,000 d; *O*, ovalbumin, 45,000 d). Dye front and free ^{125}I migrated with slice number 70. The figure represents one of four similar experiments.

with all human ovarian tumor cell lines and all surgical samples of human ovarian adenocarcinoma tested (Table II). The membrane-eluted antibodies either did not react (or reacted only weakly) with human tumor

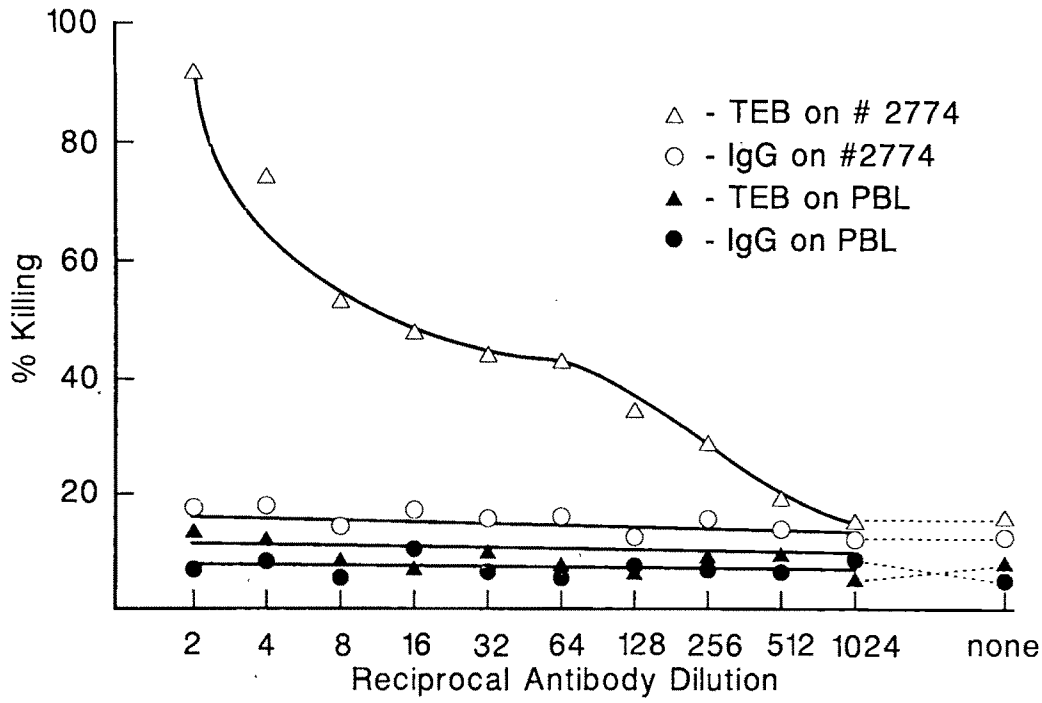

Fig. 2. Cytotoxic activity of autologous antibodies. Human ovarian tumor cell line No. 2774 or peripheral blood lymphocytes *(PBL)* (5×10^4) were washed and incubated with serial twofold dilutions of acid-eluted membrane antibodies (T.E.B.) or normal human IgG (10 μl) for 30 minutes at 37° C in microtiter plates. Guinea pig complement (10 μl) was added and cells were further incubated for 30 minutes at 37° C. The reaction was stopped with cold 0.015 mol/L ethylenediaminetetraacetic acid and 10 μl of 0.4% trypan blue was added to each well. Percent of cells taking up dye per total number of cells present was determined by light microscopy. Plotted points represent mean value of triplicates. *Open triangles*, T.E.B. on No. 2774; *open circles*, IgG on No. 2774; *solid triangles*, T.E.B. on *PBL*; *closed circles*, IgG on *PBL*.

cell lines and neoplastic tissue from colon, uterus, and breast. No reactivity was detected against normal human ovary, colon, uterus, lung, fallopian tube, or small intestine.

Characterization of autologous ovarian tumor-associated antigen (Fig. 1). Our results indicate that a tumor-associated antigen(s) is present on human ovarian tumor cells that is recognized by several of our autologous membrane-eluted antibody preparations. Antibody preparations from the fluids of four patients (T.E.B., J.B.S., E.M.D., and V.I.F.) precipitated the major bands corresponding to molecular weights of 182,000, 164,000, and 122,000 d. These bands were absent in control precipitates (buffered saline solution, W.M.J., normal IgG). These major bands may represent subunits of one antigen or three separate cell-surface tumor-associated antigens. Indeed, analysis of areas under the peaks of radioactivity demonstrates a consistent ratio of 1 : 4 : 2 (corresponding to molecular weight bands of 182,000 d : 164,000 d : 122,000 d).

Cytotoxic activity of autologous ovarian tumor-associated antigen (Fig. 2). Ovarian membrane-eluted antibodies were tested for cytotoxic activity against ovarian tumor cell lines that have positive reactivity by immunofluorescence.[14] Fig. 2 is representative of four experiments and demonstrates greater than 80% killing of cell line No. 2774 when incubated with two of our autologous antibody preparations (T.E.B. and J.B.S.). This cytotoxic activity decreased to background (20%) with dilution of antibody. No specific killing above background was demonstrated with control antibody on ovarian tumor cells or with specific antibody on unrelated cells. Similar results were obtained with cells from the serous cystadenocarcinoma line No. 7315.

Comment

The detection of ovarian cancer at an earlier stage of development might be improved if these isolated autologous antibodies prove to be as specific in vivo as they appear to be for the ovarian cancer cell in vitro. Theoretically, tumor-associated antigens could be recognized by the host and serve as a stimulus for an immune response in vivo. Numerous investigators have evidence for specific cell-mediated immunity and several laboratories have described the presence of specific antibody bound to ovarian tumor cells, suggesting that the patient has the capability of initiating an immune response against the tumor.[13, 19, 20]

Hellstrom et al.[21] describe the in vitro destruction of ovarian tumor cells by patients' lymphocytes in a colony inhibition assay. Chen et al.[22] used a leukocyte migration assay to test for hypersensitivity to tumor antigens. Levin et al.[23] describe cell-mediated immunity in the form of the blastogenic response of lymphocytes from ovarian cancer patients to crude cell extracts of ovarian tumor cells. The response of patients in remission was greater than that of normal controls, relapse patients, or patients with other cancers. These studies provide inconclusive data concerning the possibility of the in vivo response of the host to the developing tumor. However, if the tumor cells are coated with antibody in vivo, complement fixation and cell lysis should occur. Indeed, the presence of bound C3 on ovarian carcinoma cells from peritoneal effusions has been reported,[20] an indication that the first few components in the cascade are activated; however, the cells remain viable. The antibody may have its Fc fragment partially degraded by enzymes present in the fluid surrounding the tumor, there may be complement deficiencies present, or certain blocking factors may inhibit cytolysis.[24] In our laboratory two of the autologous antibody preparations were capable of complement-mediated lysis in vitro against human ovarian carcinoma cell lines but not against peripheral blood mononuclear cells or unrelated cell lines. It is possible that fresh ovarian tumor cells are resistant to complement-mediated cellular killing, whereas tissue culture adopted cells have lost this property. However, we are not aware of any previous reports in the literature in which this has occurred. We have been unable to test the autologous antibodies for the ability to mediate cellular cytotoxicity against fresh ovarian neoplastic tissue because of the spontaneous cell death that occurs on transfer of freshly dispersed tumor cells into culture media.

Several research groups have identified antigens associated with epithelial ovarian tumors and have been successful in producing antibodies in experimental laboratory animals. Most groups have reported that the ovarian tumor-associated antigens are high molecular weight. The antigens have been characterized as β-globulins; they are distinct from carcinoembryonic antigen, α-fetoprotein, ferritin, and pregnancy-associated antigens.[8, 25] The antigens are glycosylated and appear to be stable to perchloric acid extraction.[6, 9, 25] Our results suggest that autologous ovarian tumor-associated antigen may exist as a trimer with an apparent molecular weight of 468,000 d composed of three subunits of 182,000, 164,000, and 122,000 d. Alternatively, these molecular weights may represent three separate antigens.

Our experiments indicate that complete functional immunoglobulins with biologically active Fab and Fc regions were produced in vivo by patients with ovarian adenocarcinoma and that these autologous antibodies maintained cytotoxic activity against ovarian neoplastic cells in vitro. The observations that tumors continue to grow in the presence of a specific host immune response suggest the existence of mechanism(s) that enable tumors to escape immune destruction. Factors that suppress the blastogenic response of normal human lymphocytes have been detected in ascites[26] and serum[27] of patients with ovarian cancer. It has also been suggested that shedding of antigens may provide protection for the tumor by competing for the effector process of the immune system.[28, 29] In a recent report, IgG dissociated from immune complexes in ovarian ascitic fluid was able to detect significantly elevated levels of tumor-associated antigens in sera of patients with ovarian cancer compared with controls.[30] Additional work is needed to determine whether these antigens dissociated from circulating immune complexes are related to autologous ovarian tumor-associated antigen. The roles that autologous ovarian tumor-associated antigen and autologous antibodies to autologous ovarian tumor-associated antigen play in the host response to ovarian malignancy and their manipulation for detection, monitoring, and possible therapy are the goals of current investigation.

Mechanism of action of interleukin-1β in increasing corticotropin-releasing factor and adrenocorticotropin hormone release from cultured human placental cells

Felice Petraglia, MD, Gian Carlo Garuti, MD, Biagina De Ramundo, MD, Stefano Angioni, MD, Andrea R. Genazzani, MD, and Louise M. Bilezikjian, PhD

Modena, Italy, and La Jolla, California

The present study evaluated the possible effect and mechanism of action of interleukin-1β in regulating the release of corticotropin-releasing factor and adrenocorticotropin hormone from human cultured placental cells. With the use of a primary monolayer culture of human placental cells at term, the addition of interleukin-1β increased the release of immunoreactive corticotropin-releasing factor with a dose- and time-dependent effect. The intracellular concentration of both cyclic adenosine monophosphate and cyclic guanosine monophosphate increased in the presence of interleukin-1β. The addition of indomethacin, a prostaglandin synthesis inhibitor, partially reversed the effect of interleukin-1β. The same doses of interleukin-1β stimulated the release of adrenocorticotropin hormone and this effect was partially reversed by the addition of a synthetic corticotropin-releasing factor antagonist or by indomethacin. This study showed that interleukin-1β increases the release of corticotropin-releasing factor and adrenocorticotropin hormone from cultured placental cells. This effect is associated with increased intracellular cyclic nucleotide concentrations and is in part reversed by a prostaglandin synthesis inhibitor. (AM J OBSTET GYNECOL 1990;163:1307-12.)

Key words: Interleukin-1β, corticotropin-releasing factor, adrenocorticotropin hormone, cyclic nucleotides, prostaglandins, placenta

The hormonal messengers of the immune system are referred to as cytokines. Among the cytokines, the interleukins are the leukocyte-derived peptides that play a role in mediating the immune response, activating hormonal sections, and influencing cell proliferation and differentiation.[1] In particular, the biologic effects of interleukin-1 have been largely investigated. The increased activity of the hypothalamus-pituitary-adrenal axis after the administration of interleukin-1 is one of the most interesting aspects of the immune-endocrine interaction.[2] The action of interleukin-1 is mediated by the release of hypothalamic corticotropin-releasing factor and seems to be involved in stress-induced responses.[2]

In view of the increased amniotic fluid interleukin-1 levels during labor[3] and its stimulatory effect on prostaglandin production,[4] a possible role of interleukin-1 in human parturition has been suggested. Recent studies[5-7] showed that bioactive interleukin-1 is present both in trophoblastic and decidual tissue, suggesting extra sources of this cytokine in pregnant women.

A possible role of placental corticotropin-releasing factor in human parturition has also been suggested. Indeed, placental contents and circulating levels of corticotropin-releasing factor increase during labor.[8] Moreover, stress-related factors (norepinephrine, vasopressin, glucocorticoids) increase corticotropin-releasing factor release and messenger ribonucleic acid levels in cultured placental cells.[9, 10] In agreement with its neuroendocrine effect, interleukin-1α increases the release of immunoreactive corticotropin-releasing factor from cultured placental cells.[9]

Because two distinct interleukin-1 subtypes have been identified by complementary deoxyribonucleic acid sequencing: interleukin-1α and interleukin-1β, active on the same cell membrane receptors,[1] in the present study we compared the effect of these two forms of interleukin-1 on immunoreactive corticotropin-releasing factor release from cultured human placental cells. Moreover, with the aim to elucidate the mechanism of action of interleukin-1β in a system of placental cells in culture, we measured: (1) the intracellular con-

centrations of cyclic adenosine monophosphate and cyclic guanosine monophosphate; (2) the release of immunoreactive corticotropin-releasing factor in the presence of indomethacin, a prostaglandin synthesis inhibitor; and (3) the release of immunoreactive adrenocorticotropin hormone in the presence of indomethacin or of a synthetic corticotropin-releasing factor antagonist.

Material and methods

Cell culture. Placental tissue was obtained from pregnant women ($n = 8$) undergoing elective cesarean section at term. Chunks of placental cotyledons were minced, rinsed, and dissected free from the connective tissue. Stirred in a water-jacketed flask (Wheaton Scientific, Millville, N.J.) at 300 rpm at 36° C, cells were enzymatically dispersed with 0.4% collagenase (Cooper Biochemicals Inc., Malvern, Pa.) and 3000 K units deoxyribonuclease type IV (Sigma Chemical Co., St. Louis) for 1 hour. A brief exposure to 0.4% trypsin (Sigma) (stirred for 10 minutes), was followed by a filtration on 42 μm filter.[11] The dissociated cells were washed twice in a mixture of HEPES dissociated buffer and culture medium Dulbecco's Eagle modified medium nutrient mixture F12 ham (Gibco, Painsley, U.K.) supplemented with Sato's cocktail and 10% fetal calf serum (Gibco).

Recombinant interleukin-1α and interleukin-1β (Roche, Basel, Switzerland), synthetic corticotropin-releasing factor antagonist (12-41) (Dr. J. Rivier, Salk Institute, La Jolla, Calif.) or indomethacin (Sigma) a cyclooxygenase inhibitor, were used in the experiments. Cultured cells were used 5 days after plating. At this time, after the present culture method, the percentage of cytotrophoblasts that had formed syncytiotrophoblasts was lower than 50%, thus allowing the presence of both cell populations in the culture system. Cultured cells were used 5 days after plating. On the day of the experiment, cells were washed twice with HEPES-buffered Krebs-Ringer bicarbonate solution and preincubated 1 hour with 1 ml of the same solution. Interleukin-1α or interleukin-1β, corticotropin-releasing factor antagonist, or indomethacin were dissolved in sterile distilled water and prepared as a 100-fold concentrate and added in small volumes to triplicate wells that contained 1 ml of 1% bovine serum albumin HEPES-buffered Krebs-Ringer bicarbonate solution, plus bacitracin (60 μl). Vehicle-treated wells (controls) were present in each experiment. Corticotropin-releasing factor antagonist or indomethacin was preincubated for 1 hour before the addition of interleukin-1β. The same experiment was repeated at least three times in cultures prepared from different subjects.

Corticotropin-releasing factor and adrenocorticotropin hormone assay. After 3 hours' incubation, conditioned media was removed and immunoreactive corticotropin-releasing factor and immunoreactive adrenocorticotropic hormone concentrations were measured by double-antibody radioimmunoassay. Synthetic rat corticotropin-releasing factor was used to prepare the standard curve and for iodination (chloramine-T method) to produce the tracer. Rabbit antirat corticotropin-releasing factor was used at the final dilution of 1:770,000. The same buffer as for adrenocorticotropin hormone radioimmunoassay was used. The details of the incubation procedures were previously described.[11] The assay sensitivity was 2 pg/tube. The interassay and intraassay coefficients of variation were 8% and 4%, respectively.

Porcine adrenocorticotropin hormone was used to prepare the standard curve and for iodination (chloramine-T method) to prepare the tracer. Ovine antihuman adrenocorticotropic hormone serum was used at a final dilution of 1:250,000. A 0.1% bovine serum albumin, 0.1% Triton X-100 saline phosphate buffer was used to dilute all reagents. The details of the incubation procedures were previously described.[11] The assay sensitivity was 2.0 pg/tube. The interassay and intraassay coefficients of variation were 8% and 4%, respectively.

Cyclic adenosine monophosphate and cyclic guanosine monophosphate assay. On removal of the conditioned medium, total intracellular cyclic nucleotides were extracted. Cells were immediately frozen on dry ice and 1 ml of 95% ethanol containing 0.1N hydrochloric acid was added. The cells were scraped and the solution was placed in glass borosilicate tubes. This procedure was repeated twice. The extracts were stored at −20° C overnight. Centrifugation at 2500 *g* at 4° C for 45 minutes allowed denatured proteins to precipitate, whereas the supernatants were dried in a speed-vacuum concentrator (Savant, Hicksville, N.J.). The final recovery of both cyclic nucleotides was 95%, as monitored with either cyclic nucleotides labeled with iodine 125 or a known amount of standard.[12] Redissolved in sodium acetate buffer, duplicate samples were submitted to specific double-antibody radioimmunoassays for cyclic adenosine monophosphate and cyclic guanosine monophosphate.

Kits were purchased by Biomedical Technologies Inc. (Stoughton, Mass.) to measure cyclic nucleotides on the basis of methods previously described.[13] The antisera did not recognize the other cyclic and noncyclic nucleotides. The assay sensitivity was 0.005 pmole/tube for both cyclic nucleotides measured. The interassay and intrassay coefficients of variation were 8% and 3%, respectively, for cyclic adenosine monophosphate, and

9% and 4%, respectively, for cyclic guanosine monophosphate.

Results

Interleukin-1β significantly increased the release of immunoreactive corticotropin-releasing factor from cultured placental cells with a dose-dependent effect ($p < 0.01$ vs vehicle) (Fig. 1). The interleukin-1β–induced release of immunoreactive corticotropin-releasing factor was similar to that stimulated by equimolar doses of interleukin-1α (Fig. 1). Intracellular concentrations of cyclic adenosine monophosphate and cyclic guanosine monophosphate singificantly increased after the addition of interleukin-1β to the culture medium. The effect of interleukin-1β was time-dependent (the highest values were found after 30 minutes; data not shown) and dose-dependent ($p < 0.01$) (Fig. 2). Evaluated as maximum percentage increase over control values, the mean plus SD increase of cyclic guanosine monophosphate (550 + 75%) was significantly higher than that of cyclic adenosine monophosphate (185 + 45%) ($p < 0.01$).

The addition of indomethacin significantly decreased immunoreactive corticotropin-releasing factor release induced by interleukin-1β ($p < 0.01$) (Fig. 3).

Under the same experimental conditions, interleukin-1β significantly increased immunoreactive adrenocorticotropic hormone release (Fig. 4). The addition of a synthetic corticotropin-releasing factor antagonist or of indomethacin significantly decreased the interleukin-1β–induced release of immunoreactive adrenocorticotropic hormone ($p < 0.01$) (Fig. 4). When added together the corticotropin-releasing factor antagonist and indomethacin further decreased the release of immunoreactive adrenocorticotropin hormone induced by interleukin-1β ($p < 0.01$) but did not completely reverse the effect (data not shown).

Comment

The present study showed that similar to the systemic effect on hypothalamus-pituitary adrenal axis, interleukin-1β and interleukin-1α increase the release of immunoreactive corticotropin-releasing factor from cultured placental cells. This effect associated with the release of immunoreactive adrenocorticotropin hormone and both these actions of interleukin-1β are in part mediated through the activation of the prostaglandin pathway. Moreover, the increase of intracellular cyclic adenosine monophosphate and cyclic guanosine monophosphate concentrations during interleukin-1β incubation indicated that both cyclic nucleotide pathways are activated by this cytokine.

The effect of interleukin-1β on placental immunoreactive corticotropin-releasing factor release was dose dependent and its action was equipotent to that of interleukin-1α. The evidence that interleukin-1β increases immunoreactive adrenocorticotropin hormone release and that this effect is in part inhibited in the presence of a corticotropin-releasing factor antagonist indicates that interleukin-1β stimulates the local inter-

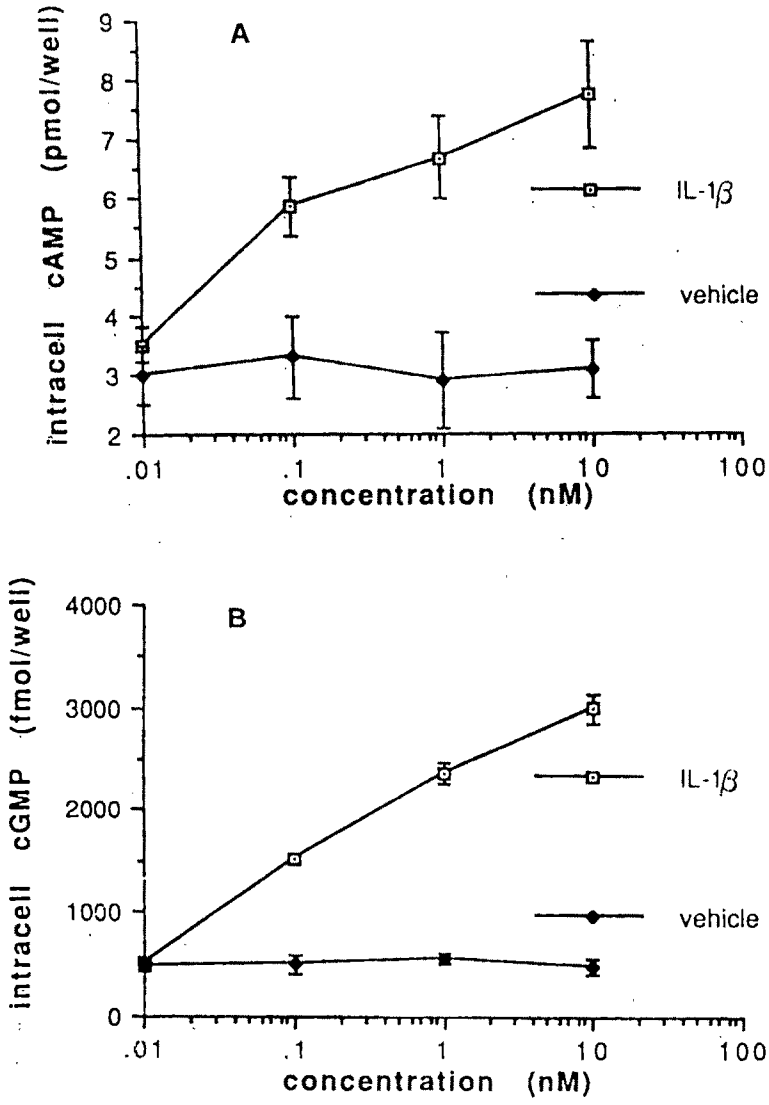

Fig. 2. Dose-dependent effect of interleukin-1β *(IL-1β)* on intracellular cyclic adenosine nucleotides *(cAMP) (panel A)* or on cyclic guanosine monophosphate *(cGMP) (panel B)*. Each point represents mean ± SE.

action between immunoreactive corticotropin-releasing factor and immunoreactive adrenocorticotropin hormone. Moreover, because indomethacin partially reverses the interleukin-1β–induced release of both immunoreactive corticotropin-releasing factor and immunoreactive adrenocorticotropin hormone, it may be suggested that interleukin-1β may modulate production of these placental hormones through prostaglandin release. This agrees with our previous finding that prostaglandins increase immunoreactive corticotropin-releasing factor and immunoreactive adrenocorticotropin hormone release from cultured placental cells.[11] The evidence that part of the interleukin-1β effect remains in the presence of indomethacin plus the corticotropin-releasing factor antagonist may be explained by the activity of other metabolites of the arachidonic acid. These findings obtained in vitro support the existence of paracrine or autocrine interactions between hormonal products in human placenta.

The increased intracellular cyclic adenosine monophosphate and cyclic guanosine monophosphate concentrations in the presence of interleukin-1β suggests a possible participation of these cyclic nucleotides in the hormonal effects of interleukin-1β in human placental cultured cells. In agreement with this hypothesis, the activation of the adenylate cyclase pathway was shown

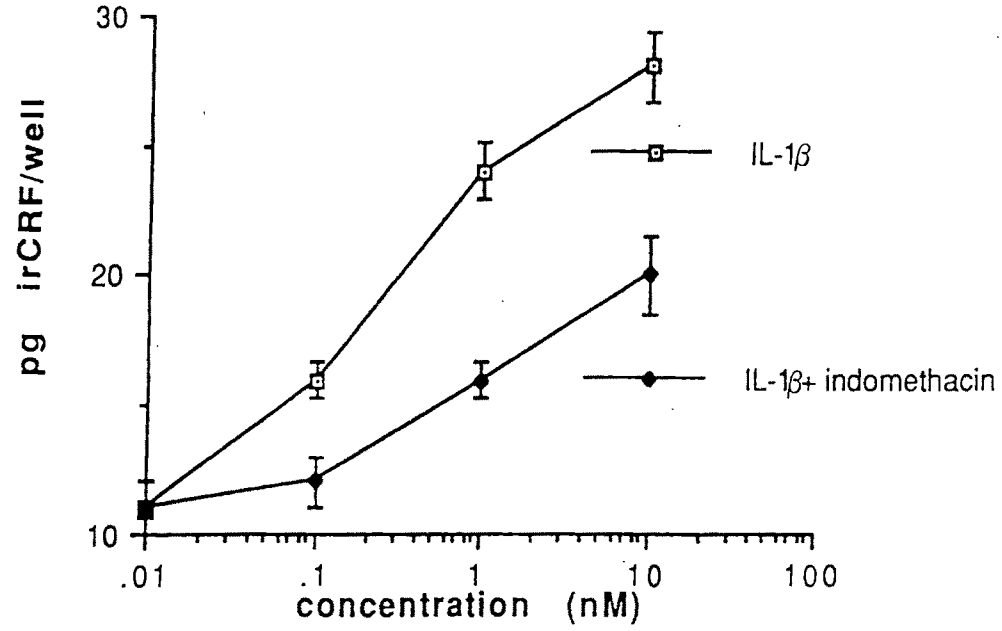

Fig. 3. Indomethacin (10 μmol) partially reverses effect of interleukin-1β *(IL-1β)* on immunoreactive corticotropin-releasing factor *(irCRF)* release from cultured placental cells. Each point represents mean ± SE.

to stimulate the release of immunoreactive adrenocorticotropic hormone from cultured placental cells.[11]

The possible participation of interleukin-1 to the mechanisms of control of placental hormone production was recently supported by evidence that the addition of interleukin-1 to trophoblast cultures stimulated the release of human chorionic gonadotropin.[14]

The presence of interleukin-1 in trophoblast and decidua[5-7] supports a possible local source of the cytokines in modulation of placental hormone release. Hu-

man decidua also produces tumor necorsis factor-α, another cytokine, which shares several biologic properties with interleukin-1.[15] Therefore decidual or placental interleukin-1 may stimulate trophoblast cells to release corticotropin-releasing factor and it may be suggested to contribute to the increase of plasma corticotropin-releasing factor and adrenocorticotropin hormone levels during labor.[8] Moreover, the observation that both interleukin-1 and corticotropin-releasing hormone increase prostaglandin synthesis in cultured human decidual tissue[4, 16] further sustains the hypothesis that an immune-endocrine interaction may play a role in human parturition. This hypothesis has been mainly supported by the observations obtained in preterm labor.[3, 15, 16] However, the present and previous results were obtained in vitro and at and the present time it is speculative to hypothesize that this interaction occurs in vivo.

In conclusion, the present results show that interleukin-1β stimulates the corticotropin-releasing factor, adrenocorticotropin hormone axis in a system of cultured placental cells involving a prostaglandin pathway, thus suggesting the existence of an immune-hormonal interaction in human placenta.

Hypoxic acidemia, hyperviscosity, and maternal hypertension do not affect the umbilical arterial velocity waveform in fetal sheep

Robert J. Morrow, MD, S. Lee Adamson, PhD, Shelley B. Bull, PhD, and J. W. Knox Ritchie, MD

Toronto, Ontario, Canada

The effect of hypoxic acidemia, hyperviscosity, and maternal hypertension on the umbilical arterial velocity waveform was studied in 23 chronically catheterized fetal sheep. Fetal hypoxic acidemia induced by lowering the maternal inspired oxygen concentration (n = 7) caused no change in the ratio of systolic/diastolic blood velocity even when fetal arteral pH was as low as 6.8. Fetal blood hyperviscosity (n = 7) induced by exchange transfusion with packed maternal blood cells increased placental vascular resistance by ≥50% but had no significant effect on the systolic/diastolic ratio. Similarly, maternal hypertension induced by intravenous infusion of angiotensin II to the ewe (n = 9) did not affect the systolic/diastolic ratio despite a 50% increase in maternal arterial blood pressure. We conclude that umbilical arterial velocity waveform abnormalities observed in growth-restricted human fetuses are probably not a direct result of fetal hypoxemia or hyperviscosity or maternal hypertension. (AM J OBSTET GYNECOL 1990;163:1313-20.)

Key words: Doppler ultrasonography, umbilical blood flow, intrauterine growth restriction, fetal assessment

Doppler ultrasonography is widely used in obstetrics to investigate blood velocity waveforms in the umbilical artery of human fetuses mainly because of the observation that the umbilical velocity waveform is often dramatically altered when fetal growth restriction is present.[1, 2] An abnormal velocity waveform is characterized by low, zero, or reversed blood velocity during diastole, relative to that during systole. Because abnormalities in the umbilical velocity waveform have been associated with poor neonatal outcome,[3, 4, 5] it has been suggested that the observation of an abnormal waveform should lead to a clinical intervention ranging from increased surveillance[6] to premature delivery of the fetus.[7] Despite these recommendations, it is not known how abnormal waveforms relate to the physiologic status of the fetus.

Pregnancies with fetal intrauterine growth restriction exhibit a higher incidence of hypoxia,[8, 9] hyperviscosity,[10] and pregnancy-induced hypertension,[11] and are more likely to have abnormal umbilical arterial velocity waveforms than are normally grown fetuses.[2] Increased placental vascular resistance has been shown to induce abnormal umbilical arterial velocity waveforms in fetal sheep[12, 13] and there is histologic evidence to suggest that placental resistance may be higher than normal in growth-restricted human fetuses.[14, 15] Thus elevated placental vascular resistance appears to play an important role in the induction of umbilical waveform abnormalities in growth-restricted fetuses. However, it is not known whether other factors could also cause umbilical arterial velocity waveform abnormalities. Because hypoxia, hyperviscosity, and maternal hypertension are more common in growth-restricted fetuses, we investigated whether these factors could play a role in the production of abnormal umbilical arterial waveforms.

Material and methods

We developed and used a chronically catheterized fetal sheep preparation with Doppler crystals implanted on the umbilical artery for these studies. First we compared Doppler signals obtained with the implanted crystals with those obtained with a commonly used clincial Doppler machine to ensure that the signals obtained were relevant to the clinical situation. We then

performed experiments on three different groups of animals. In the first group, maternal hypoxia was used to induce fetal hypoxemia that was sufficient to cause progressive fetal acidosis. In the second group, fetuses were exchange transfused with packed maternal red blood cells until fetal blood viscosity was increased by ≥50%. In the third group, three dose levels of angiotensin II were infused to the ewe over 15 minutes to induce maternal hypertension.

General procedures. Anesthesia of pregnant ewes between 120 and 125 days' gestation was induced with thiopental sodium (1 gm administered intravenously) and was maintained with halothane and nitrous oxide in oxygen. The hind part of the fetus was withdrawn through a uterine incision and a midline incision was made in the fetal abdomen below the umbilicus to expose an umbilical artery. A flexible silicone cuff that contained a Doppler crystal mounted at approximately 45° to the direction of blood flow (20 MHz; Crystal Biotech, Halliston, Mass.) was sutured in place around one of the umbilical arteries. Vasospasm caused by manipulation of the artery was reduced by applying a muscle relaxant to the artery during surgery (papaverine hydrochloride, Frosst, Kirkland, Quebec, Canada). Two polyvinyl catheters were inserted into the femoral artery so that their tips lay in the aorta. They were used to sample blood for blood gas analysis, to withdraw samples containing radioactive microspheres, and to continuously monitor blood pressure. Another catheter was inserted into the inferior vena cava via the femoral vein and it was used to continuously monitor blood pressure and to infuse radioactive microspheres for flow measurements. Blood pressure levels were measured relative to amniotic pressure, which was monitored by means of a catheter sutured to the fetal abdomen.

Ewes were given an analgesic agent (Levo-Dromoran, levorphanol tartrate preparation, 2 mg subcutaneously) after surgery, and prophylactic antibiotics (Pen-di-Strep, Rogar, Canada) for 3 days postoperatively. Experiments were performed ≥5 days after surgery. Surgery and experiments were conducted in accordance with guidelines prescribed by the Canadian Council on Animal Care.

Vascular catheters were connected to pressure transducers (Model P23ID, Spectramed, Oxnard, Calif.) and the Doppler leads were connected to a Doppler flow meter (Model VF-1, Crystal Biotech). Blood pressure levels, heart rates, and umbilical arterial blood velocities were continuously monitored on a polygraph (Grass Instruments, Quincy, Mass.). Maternal and fetal arterial blood samples were obtained at intervals throughout the experiments and were measured immediately for blood gas and pH levels on a blood gas analyzer (Model 170, Corning Medical, Medfield, Mass.). Maternal and fetal bood gas values were temperature-corrected to 38° C and 39° C, respectively. Arterial oxygen content was measured with a co-oximeter (Model 2500, Corning Medical).

Placental blood flow was measured with the radioactive microsphere technique.[16] Immediately after starting collection of arterial reference samples with a syringe pump (2 ml · min^{-1} over 2.5 minutes), microspheres (15 μm, 3M, St. Paul, Minn.) labeled with scandium 46, cerium 141, chromium 51 or niobium 95 were introduced into the inferior vena cava over 20 seconds. Radioactivity in the placenta was counted (Model 1282 CompuGamma, LKB-Wallac, Turku, Finland) and flows were derived as previously described.[16] Placental vascular resistance was calculated by dividing the aorta to vena cava pressure gradient by the placental blood flow.

In all experiments a logarithmic transformation was performed on umbilical blood flow and placental vascular resistance to normalize their distributions. The analysis of the diastolic/systolic ratio, the inverse transformation of the systolic/diastolic ratio (S/D), gave identical conclusions so only the S/D ratio is presented. All data are presented as the mean ± SEM of the untransformed data.

Series I—validation of model (n = 6). After surgery, while ewes were still anesthetized, the S/D ratio was simultaneously measured from the umbilical artery with two instruments: our pulsed Doppler device that uses implanted crystals and a transcutaneous, continuous-wave Doppler instrument commonly used clinically (4 MHz; Multigon, Mount Vernon, N.Y.). The sample volume (1 mm^3) on the pulsed Doppler instrument was scanned across the vessel until the maximum velocity was obtained; thereafter the maximum velocity signal was monitored on an oscilloscope. The Doppler beam of the transcutaneous instrument was directed toward the umbilical arteries, which had been located before closure of the uterus, and the direction was then adjusted to obtain the characteristic umbilical waveform.[17] The Doppler signal from the transcutaneous device was continuously displayed on a video display screen. S/D ratios were measured from at least five cardiac cycles simultaneously frozen on the oscilloscope and the video display screen. Electronic calipers were used to measure the S/D ratio on the frozen video image obtained with transcutaneous Doppler ultrasonography. The S/D ratio from the implanted crystals was measured from a photograph of the oscilloscope screen.

Blood flow to the placenta was measured with radioactive microspheres (as described above) after at least 5 days' recovery from surgery. The flow distribution to each umbilical artery was measured to ensure that blood flow through this highly vasoactive vessel was not altered by the presence of the cuff. Four measurements

of blood flow were made in each of six fetuses. At postmortem examination, one umbilical artery was randomly selected and cannulated. Methylene blue dye was infused so that the cotyledons in the distribution of that artery were stained blue. Those in the distribution of the other artery remained unstained. The cotyledons that were only partly stained were excluded from this analysis (but were not excluded from the determination of total placental blood flow described above). Blood flow through each umbilical artery was calculated and expressed in milliliters per minute per 100 gm cotyledon wet weight.

Differences between the two Doppler methods and between the two umbilical artery blood flows were assessed with graphic techniques and estimates of the range of values in which 95% of differences in a single measurement are expected to lie.[18]

Series II—hypoxic acidemia (n = 7). An additional catheter (5 mm outer diameter) was inserted nonocclusively into the trachea of the ewe through a small incision below the fourth cricoid cartilage. Gas mixtures were passed through this catheter to manipulate maternal inspired oxygen concentration.[19]

During hypoxemia, the flow rate of nitrogen into the maternal tracheal catheter was adjusted to induce a 50% reduction in fetal arterial oxygen content. Carbon dioxide was added to the nitrogen infusion to maintain a constant arterial P_{CO_2}. During baseline measurements, before the induction of hypoxemia, air was infused at the same flow rate (about 16 L · min^{-1}) through the tracheal catheter. Fetal blood gas values and cardiovascular variables were measured three times at 5-minute intervals and blood flow was measured once during the baseline period. During hypoxemia, the gradual development of fetal acidemia was monitored by measurement of fetal blood gas and pH levels every 30 minutes. When the fetal pH reached 7.2, 7.0, and 6.8 the measurement protocol described during the baseline period was repeated. One fetus died between pH 7.2 and 7.0, two fetuses died between pH 7.0 and 6.8, and data are missing for one fetus at pH 7.0 because of technical reasons.

The data for each animal were summarized by averaging the three measurements made within each of four periods: baseline, pH ≤ 7.2, pH ≤ 7.0, and pH ≤ 6.8. Each of the averages at pH ≤ 7.2 and at pH ≤ 7.0 were compared with the baseline average with a paired Student t test. Statistical significance was then assessed at the 2.5% rather than the 5% level to control for multiple testing. Data obtained at pH ≤ 6.8 was not tested for significance because values reflected terminal changes and because the sample size was depleted (n = 2 or 4, depending on the variable).

Series III—fetal hyperviscosity (n = 7). Blood was collected from adult donor sheep into plastic blood bags (Fenwal, Division of Travenol Labs Inc., Deerfield, Ill.) containing citrate phosphate dextrose adenine solution and heparin. The bags were centrifuged and the plasma was removed.

Blood viscosity was measured at 39° C as a function of shear rate with a cone and plate viscometer (Wells-Brookfield, Brookfield Engineering Laboratories Inc., Stoughton, Mass.). Three baseline viscosity measurements were made on heparinized fetal blood drawn at 15-minute intervals. The packed red blood cells were then introduced into the inferior vena cava while blood was simultaneously withdrawn at the same rate from the fetal aorta (3 ml · min^{-1}; Harvard Apparatus, South Natick, Mass.). The transfusion was continued until the fetal blood viscosity was increased by ≥50%. After a 1-hour equilibration period, measurements were repeated at the elevated viscosity.

A paired Student t test was used to compare the average of the three baseline measurements with the average of the three measurements made at increased viscosity.

Series IV—maternal hypertension (n = 9). An additional vascular catheter was implanted in the maternal femoral artery so that blood pressure could be monitored.

Angiotensin II (Ciba Geigy, Toronto) in isotonic saline solution was infused for 15 minutes via the femoral vein of the ewe at doses of 5, 10, and 15 μg · min^{-1} at a flow rate of 15 ml · min^{-1}. These doses were chosen because a dose of 11.5 μg · min^{-1} had previously been shown to cause elevated maternal blood pressure and changes in the fetal circulation suggesting increased placental vascular resistance.[20] Isotonic saline solution infused at 15 ml · min^{-1} was used as a control. Each 15-minute infusion was followed by a 45-minute recovery period before the next dose was infused. The order of infusions was randomized.

Two measurements were made before each infusion (−10 and 0 minutes) and during each infusion (+10 and +15 minutes). The two values within each time period were similar so they were averaged to reduce variability in the data. The difference between measurements obtained before and during each infusion was used for subsequent statistical analysis. Repeated measures analysis of variance was used to determine the effect of different dosage levels of angiotensin II for animals with complete information for all infusions (n = 6), followed by paired Student t tests that incorporated all available information.

Results

Series I—validation of implanted crystals. The S/D ratios obtained from the umbilical artery with the internal and the external Doppler instruments were highly correlated (r = 0.98) and differences between

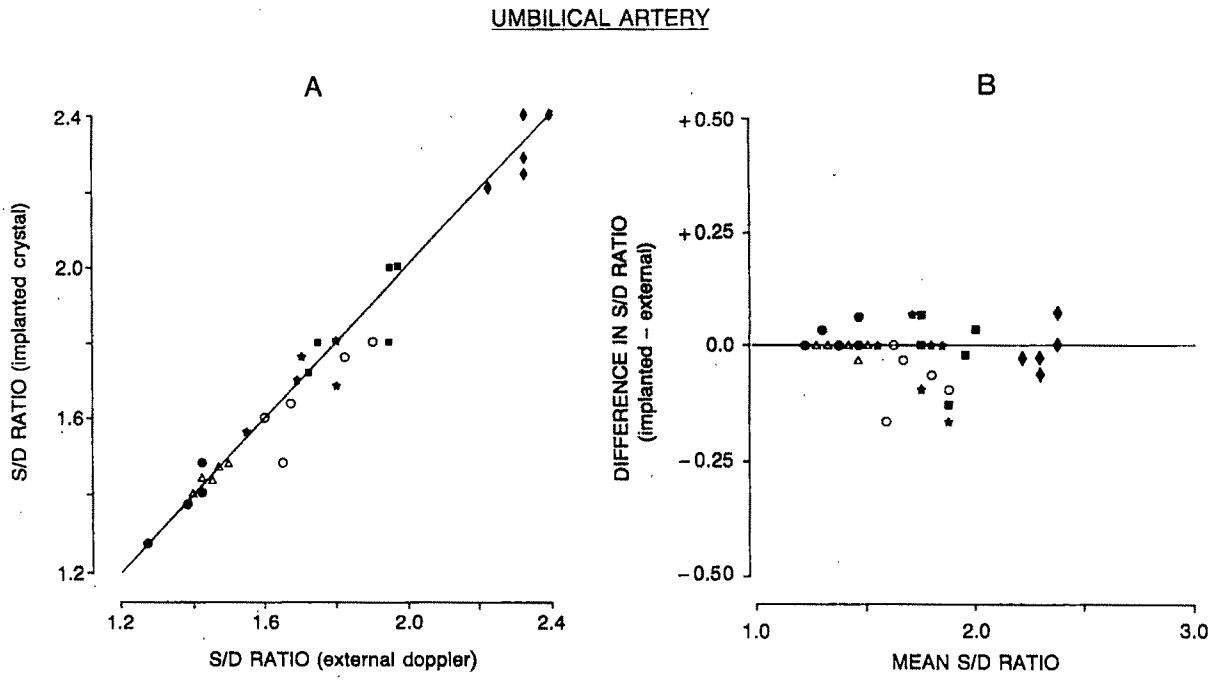

Fig. 1. A, Comparison of S/D ratio in umbilical artery with implanted Doppler crystal and clinical Doppler instrument (external). Each symbol represents individual animal. *Solid line* shows line of identity. **B,** Plot of differences between S/D ratio obtained with external and implanted Doppler techniques. That values lie close to zero throughout range of mean S/D ratio indicates there was no systematic difference between methods of measurement.

the two measurements were small (Fig. 1); 95% of the differences would be expected to be within ±0.16. The overall mean difference between the two signals was 0.02 and the size of the difference did not depend on the size of the ratio ($r = 0.11, p = 0.84$). Thus, the two methods of measurement were in close agreement.

The mean blood flow to the part of the placenta supplied by the artery monitored by the Doppler crystal was 145 ml · min^{-1} per 100 gm of placenta compared with 153 ml · min^{-1} per 100 gm of placenta in the other artery. The correlation coefficient between flows measured in each artery was 0.90 and, expressed as a percentage difference, the overall mean difference was 2.8% with 95% of individual differences expected to lie within ±20%. There was no significant difference between the weight of placenta supplied by each artery.

Series II—hypoxic acidemia. The mean fetal pH before induction of hypoxemia was 7.37 ± 0.01. The mean pH at each of the measurement points were 7.13 ± 0.02 (pH ≤ 7.2), 6.95 ± 0.02 (pH ≤ 7.0), and 6.75 ± 0.03 (pH ≤ 6.8). During hypoxemia, the oxygen content was reduced from 7.8 ± 0.3 ml · dl^{-1} to 2.8 ± 0.1 ml · dl^{-1} at the first measurement point (pH ≤ 7.2) and it remained at <50% of baseline for the duration of the hypoxic period (approximately 8 hours). The mean Pao_2 was 22 ± 1 mm Hg at baseline and it decreased to 11 ± 1 mm Hg at the first measurement point. The mean $Paco_2$ showed little change from the baseline value of 49 ± 2 mm Hg although it decreased slightly during hypoxemia ($Paco_2$ at the first measurement point was 44 ± 2 mm Hg).

The fetal arterial blood pressure, heart rate, and placental vascular resistance did not significantly alter with increasing acidosis (at pH ≤ 7.2 and pH ≤ 7.0). The systolic, diastolic, and mean umbilical velocities all showed small but significant decreases with progressive acidosis although the decrease in umbilical blood flow was not statistically significant (Table I). Nevertheless, the S/D ratio did not significantly change from the baseline value of 2.1 ± 0.1 with progressive acidosis down to pH ≤ 7.0 (Fig. 2). In all cases, however, we observed an increase in S/D ratio when hypotension and bradycardia developed in the fetus shortly before death. At pH ≤ 6.8, two of the four fetuses were hypotensive (arterial pressure levels were 28 mm Hg and 17 mm Hg) and bradycardic (heart rates were 108 and 80 min^{-1}) and both fetuses had zero diastolic velocities. The remaining two fetuses at pH ≤ 6.8 had arterial pressure levels of 44 and 27 mm Hg, heart rates within the normal range (153 and 172 min^{-1}), and S/D ratios of 3.7 and 3.8, respectively.

Series III—fetal hyperviscosity. Fetal hematocrit was 30% ± 3% before exchange transfusion with packed maternal blood cells. After transfusion the he-

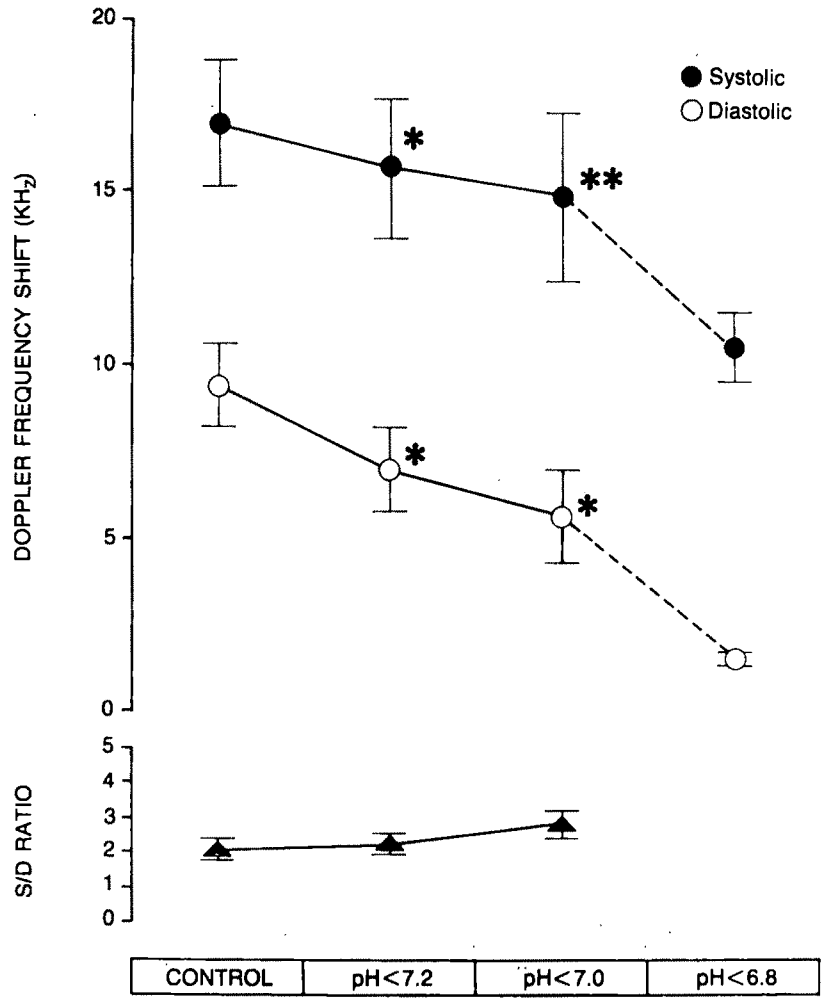

Fig. 2. Systolic and diastolic Doppler frequency shift (proportional to blood velocity) and S/D ratio are shown for both control and progressive acidemia. Only four of seven fetuses survived to pH ≤ 6.8 so data points are joined by *dashed lines* (these data were not subjected to statistical analysis). *$p \leq 0.025$ compared with control. **$p = 0.002$ compared with control.

matocrit was increased to 45% ± 2%. The mean blood viscosity at the three shear rates tested (90, 255, and 450 seconds^{-1}) was 2.3 ± 0.2 cP before and 3.8 ± 0.2 cP after transfusion. This increase caused a significant 50% increase in placental vascular resistance (Table II).

Hyperviscosity did not significantly affect the umbilical artery S/D ratio; however, the mean velocity and the diastolic velocity were both significantly reduced and the systolic velocity showed a decreasing trend ($p = 0.07$) (Table II). The mean fetal arterial pressure increased significantly but there was no significant change in fetal heart rate or umbilical blood flow. Fetal Pa_{O_2}, Pa_{CO_2}, oxygen content, and pH were not significantly altered from control values of 20 ± 1 mm Hg, 50 ± 2 mm Hg, 6.1 ± 0.4 ml · dl^{-1}, and 7.36 ± 0.01, respectively, by the exchange transfusion.

Series IV—maternal hypertension. Maternal mean arterial blood pressure was 91 ± 8 mm Hg during infusion of saline solution. During infusions of 10 and 15 μg · min^{-1} angiotensin II, maternal arterial blood pressure levels increased to 125 ± 5 and 136 ± 7 mm Hg, respectively. Mean maternal heart rate, P_{O_2}, oxygen content, P_{CO_2}, and pH were not significantly affected by angiotensin II infusions.

The umbilical S/D ratio during infusion of saline solution was 2.4 ± 0.2 and it did not significantly change during angiotensin II infusion at any dosage studied. There were no significant changes in mean fetal arterial blood pressure, heart rate, placental blood flow, placental vascular resistance, or blood gas and pH values during maternal infusions of angiotensin II.

Comment

Continuous monitoring of the umbilical arterial velocity waveform in the conscious animal was readily achieved with implanted Doppler crystals. We have

demonstrated that waveforms recorded by this method are similar to those obtained with a transcutaneous, continuous-wave Doppler instrument. We have also shown that the presence of the cuff around the artery does not affect blood flow through this highly vasoactive vessel. Although the placental anatomy of the sheep differs from that of human beings we found that waveform shapes and S/D ratios in the sheep umbilical arteries were similar to those observed in the human fetus near term.[1, 17] Furthermore, the umbilical arterial S/D ratio in fetal sheep decreases with advancing gestational age[21] in a manner similar to that in human beings.[17] Thus the described fetal sheep preparation provides a suitable model for studying the cause of abnormal umbilical arterial waveforms.

We have shown that hypoxic acidosis down to a pH of 7.0 does not cause a significant change in the umbilical arterial velocity waveform. This suggests that redistribution of blood flow that occurs in response to hypoxic acidosis[22] does not affect the umbilical arterial waveform. However, the S/D ratio ultimately increased in all fetuses when the pH ≤ 6.8. This may have been mediated by a decrease in myocardial contractility caused by acidemia.[23] Although the mechanism is not known, diastolic velocity decreased to zero in all fetuses when hypotension and bradycardia occurred before fetal death. Because changes in the S/D ratio were only marked when the fetus was near death, the umbilical artery velocity waveform does not appear to provide an early warning of developing fetal hypoxic acidosis. This finding is in agreement with Weiner[24] who studied the relationship between umbilical arterial S/D ratio and the umbilical venous acid-base status in human fetuses and concluded that an abnormal umbilical arterial S/D ratio was not a sufficiently accurate indicator of fetal acid-base status to form the basis for clincial management.

We have increased viscosity by 60% and have observed no change in the umbilical waveform shape as measured by the S/D ratio. This result indicates that it is highly unlikely that the association between the much smaller elevation in blood viscosity and abnormal umbilical arterial velocity waveforms observed by Giles and Trudinger[25] in human subjects was a direct cause-effect relationship.

Umbilical arterial waveforms and fetal placental resistance did not change even during large increases in maternal arterial blood pressure induced by maternal angiotensin II infusion. Pressure in the maternal blood vessels of the sheep placenta influence fetal placental vascular resistance presumably by causing partial collapse of the fetal placental vessels.[26] Thus we hypothesized that an increase in maternal arterial blood pressure could increase fetal placental vascular resistance and that this effect could play a role in producing the umbilical arterial waveform abnormalities observed in

patients with pregnancy-induced hypertension. Because no significant change in umbilical vascular resistance was observed, it is possible that the increase in central arterial pressure was not transmitted to the small exchange vessels of the maternal placenta. Whether high central pressures are transmitted to the placental microcirculation in hypertensive pregnant women is not known. The absence of a direct effect of maternal blood pressure on umbilical waveforms may explain why abnormal waveforms are often not observed in women with chronic hypertension or mild pregnancy-induced hypertension.[27]

The absence of significant fetal cardiovascular effects during maternal angiotensin II infusion is consistent with studies that concluded that angiotensin II does not cross the placenta in an active form[28, 29] but contradict those of Perales et al.[20] Although we used a similar dose of angiotensin II and induced a similar increase in maternal arterial blood pressure, we were unable to reproduce the significant increase in fetal blood pressure and decrease in heart rate described by Perales et al.[20] The reason for the discrepancy in results is not known.

There is growing evidence that the umbilical S/D ratio reflects placental vascular resistance.[12, 13, 30] However, we caused a substantial increase in the placental vascular resistance by increasing blood viscosity but the S/D ratio was not significantly altered. The 50% increase in resistance should have been sufficient to produce an effect if the waveform were sensitive to viscosity inasmuch as a 40% increase in placental vascular resistance caused by placental embolization had a significant effect.[30] It is noteworthy that, like viscosity, an increase in placental vascular resistance caused by umbilical arterial vasoconstriction also has no effect on the umbilical arterial velocity waveform.[13] Thus, the mechanism by which placental vascular resistance is increased is important in determining whether waveform shape is affected.

In conclusion, we have demonstrated that hypoxic acidemia in the sheep fetus does not significantly affect the umbilical arterial velocity waveform until fetal death is imminent. Thus a fetus may be hypoxic and acidotic, but still have a normal waveform if the placental ultrastructure is normal. Normal waveforms are also observed when resistance to fetal placental blood flow is increased either by hyperviscosity or by vasoconstriction of the umbilical arteries.[13] On the other hand, when peripheral placental resistance is elevated by embolization with microspheres, the waveform abnormalities observed in growth-restricted human fetuses are reproduced.[12, 18] Thus apart from cardiovascular collapse before death, it appears that an abnormal umbilical arterial velocity waveform is a very specific indicator of elevated resistance within the small vessels of the fetal placenta and should be used with caution as a more general indicator of fetal condition.

We thank Dr. C. E. Musclow for her assistance in preparing packed blood cells and for measuring fetal blood viscosity.

A progesterone-induced blocking factor corrects high resorption rates in mice treated with antiprogesterone

Julia Szekeres-Bartho, MD, PhD,[a] G. Chaouat, MD, PhD,[b] and R. Kinsky, DV, PhD[b]

Pecs, Hungary, and Paris, France

Earlier we showed that because of the presence of functional progesterone receptors, lymphocytes of healthy pregnant women produced an immunomodulatory protein in the presence of progesterone, whereas those of nonpregnant persons did not. Progesterone-treated murine pregnancy lymphocytes release a similar factor. The present study reveals the biologic significance of this finding. Treatment of BALB/c mice that were 8 days pregnant with a progesterone receptor blocker (RU 486) resulted in 100% resorption of the fetuses. Simultaneous administration of the supernatant from progesterone-treated murine pregnancy spleen cells restored the resorption rate to the original 6% observed in untreated control animals. These data suggest that functional lymphocytic progesterone binding sites are needed for the maintenance of normal pregnancy. Because of the blockage of progesterone receptors and the consequent inability of the lymphocytes to produce the progesterone-induced blocking factor, abortion is initiated by immune factors. The fact that administration of the preformed blocking factor counteracted the effect of antiprogesterone treatment suggests that progesterone-mediated immunosuppression is needed for the maintenance of normal gestation. (Am J Obstet Gynecol 1990;163:1320-2.)

Key words: Progesterone receptor block, abortion, progesterone-dependent immunomodulation

There is now ample evidence that the maternal immune system recognizes a semiallogeneic conceptus.[1, 2] Local mechanisms can in turn prevent potentially harmful antifetal immune reactions, thus assuring a normal outcome of pregnancy.[3] Progesterone is essential for the maintenance of mammalian gestation. In general, estrogens promote and progesterone inhibits uterine contractility, interfering in this way with the initiation of labor. Progesterone further affects in vitro lymphocyte reactivity.[4] We have shown that human pregnancy lymphocytes (unlike nonpregnancy ones) possess specific progesterone binding sites.[5, 6] When exposed to progesterone, these lymphocytes release a protein[7] endowed with diverse immunomodulatory properties.[8]

This protein appears in the serum of pregnant women and its concentration shows a correlation with

*Significantly different from RU 486-treated mice at $p < 0.001$.

the success of pregnancy.[9] RU 486 mifepristone is a competitive antagonist of progesterone that blocks progesterone and to a certain extent glucocorticoid binding sites, thus leading to abortion in the early phase of pregnancy.[10] Data obtained by testing lymphocyte function of women treated with the progesterone receptor blocker ZK98734 suggests that the block of lymphocyte progesterone receptors correlates better with the abortive effect than the block of trophoblastic receptors.[11]

On the basis of these data we assume that progesterone-mediated immunosuppression is crucial for the maintenance of pregnancy. We present data that show a possibility to overcome receptor blocking by supplying in vivo the progesterone-induced immunomodulatory substance lacking in RU 486—treated pregnant females.

Material and methods

Production of the progesterone-induced blocking factor. C3H mice that were 12 days pregnant (Institute de la Recherche Scientifique sur le Cancer [IRSC], Villejuif, France) were killed and the spleens were harvested. Lymphocytes were isolated in Ficoll-Paque gradient, washed three times, and treated at a cell density of 5×10^6 viable cells per milliliter with 10 μg/ml of progesterone for 3 hours. At the end of the incubation period, supernatants were collected and dialyzed overnight at 4° C against 500× volume medium to eliminate progesterone. Radioimmunologic determination of progesterone revealed that almost 100% of the progesterone was depleted from the supernatants by dialysis.

Supernatants of progesterone-treated lymphocytes from virgin C3H mice and those of untreated pregnancy spleen cells were used as controls.

Treatment of pregnant mice with RU 486 and the progesterone-induced blocking factor. BALB/c mice were obtained from the IRSC breeding center (Centre National de la Recherche Scientifique, Villejuif, France). Successful matings were checked daily by vaginal plug examinations, and mated females were randomly separated into experimental and control groups.

At 8 days' gestation 2 mg/kg RU 486 was administered intraperitoneally alone or with 0.5 ml of supernatant of progesterone-treated pregnancy spleen cells or control supernatants. Experimental and control female mice were killed on day 10 of pregnancy and living and resorbing embryos were counted.

Statistical analysis. The data were analyzed by the χ^2 test.

Results

Treatment of BALB/c mice that were 8 days pregnant with a single 2 mg/kg dose of RU 486 resulted in 100% resorption of the fetuses. Simultaneous intraperitoneal administration of 0.5 ml of the supernatant of progesterone-treated pregnancy spleen cells prevented the abortive effect of the antiprogesterone (i.e., it restored the resorption rate to the original 6% observed in untreated control animals). The supernatants of untreated pregnancy spleen cells and those of progesterone-treated spleen cells from virgin mice were without effect (Table I).

Comment

Progesterone has been shown to exert immunologic effects in vitro.[4] This hormone is produced in large quantities during pregnancy and reaches high concentrations locally at the fetomaternal interface, thus it might be involved in local immunosuppression. Earlier we showed that progesterone-treated lymphocytes of healthy pregnant women produce a 34 kd immuno-

modulatory protein.[7] The in vitro effects of this substance include suppressor cell generation and inhibition of natural killer and natural cytotoxic activity.[8] The concentration of this factor was significantly higher in the sera of healthy pregnant women than that in the sera of nonpregnant persons or pregnant women with clinical symptoms of threatened abortion or threatened preterm delivery.[9]

The termination of pregnancy was found to be associated with increased natural cytotoxic activity of the lymphocytes.[12] The serum concentration of the blocking factor correlated well with the outcome of pregnancy, as well as with the natural killer blocking potential of the sera.[9] Therefore it seemed likely that the in vivo action of the protein involved blockage of natural killer activity and that the blockade of natural killer activity was needed for the maintenance of normal pregnancy. Natural killer activity might be involved in fetal tissue destruction as well as the blockage of blood supply and the induction of smooth muscle contraction by some of their secreted products (e.g., tumor necrosis factor).[13] This hypothesis was further supported by the fact that administration of the blocking factor significantly reduced the high resorption rate induced by the transfer of natural killer cells to pregnant BALB/c mice (unpublished observation).

Recently we demonstrated progesterone receptors in lymphocytes of healthy pregnant women but not in those of healthy nonpregnant persons.[5] Blockage of progesterone receptors both in human beings and animal models results in the cessation of pregnancy,[10] and the production of the blocking factor by human lymphocytes is progesterone receptor dependent.[5, 8]

Recently we showed in a study with human beings that at a certain dose progesterone receptor blockers affected trophoblastic and lymphocytic binding sites to a different extent, and that the involvement of lymphocytic progesterone receptors showed a higher degree of correlation with the success or failure of the treatment than that of the trophoblastic receptors.[11]

This study shows that administration of the preformed progesterone-induced blocking factor counteracts the abortive effect of progesterone receptor block. These data support the following hypothesis: normal pregnancy lymphocytes express specific binding sites for progesterone. This allows the production of the blocking factor when lymphocytes are exposed to the hormone. In the murine model the abortive effect of progesterone receptor block was overcome by the suppressive substance. The present study shows that the progesterone-induced immunologic blocking factor in addition to its in vitro immunomodulatory effects is able to substitute the immunologic effects of progesterone, and that this alone could alter the resorption rate in progesterone-deprived animals. Therefore it seems likely that progesterone-mediated immunosuppression has a role in the maintenance of gestation.

Effects of magnesium and isradipine on contractile activation induced by the thromboxane A_2 analog U46619 in human uteroplacental arteries in term pregnancy

Kristjar Skajaa, MD,[a]* Danny Svane, MD,[a] Karl-Erik Andersson, MD, PhD,[b] and Axel Forman, MD, PhD[a]

Århus, Denmark, and Lund, Sweden

The effects of Mg^{++} and the dihydropyridine calcium channel blocker isradipine on contractions induced by the thromboxane A_2 mimetic U46619 were studied in isolated human uteroplacental arteries. In all preparations investigated U46619 10^{-10} to 10^{-6} mol/L induced concentration-related contractile responses. In maternal vessels U46619 produced a biphasic concentration-response curve, whereas the compound in fetal vessels produced a sigmoid concentration-response curve parallel to that of prostaglandin $F_{2\alpha}$. Mg^{++} (1.0 to 6.0 mmol/L) and isradipine (10^{-10} to 10^{-5} mol/L) both relaxed U46619-induced contractions by up to about 40%. In preparations precontracted by U46619 and exposed to isradipine 10^{-6} mol/L, addition of Mg^{++} 6.0 mmol/L consistently produced a further small relaxation. Removal of the endothelium or pretreatment with indomethacin 10^{-6} mol/L or digoxin 10^{-6} mol/L did not influence the inhibition produced by Mg^{++} or isradipine. In vessels pretreated in Ca^{++}-free medium Mg^{++} 6.0 mmol/L depressed and isradipine abolished responses to Ca^{++} (0.01 to 4.0 mmol/L) after depolarization with K^+ 124 mmol/L. In maternal and fetal arteries stimulated with U46619, however, Mg^{++} 6.0 mmol/L and isradipine 10^{-6} mol/L produced a similar, partial inhibition of responses to Ca^{++} (0.01 to 4.0 mmol/L). Mg^{++} seems to inhibit transmembrane Ca^{++} influx, although less efficiently than the dihydropyridine calcium antagonist isradipine. In addition, Mg^{++} may interfere with Ca^{++} at intracellular binding sites. Provided that preeclampsia comprises enhanced vascular actions of thromboxane A_2, the present results support the established use of Mg^{++} in the treatment of this condition and suggest that calcium antagonists are of potential benefit. (AM J OBSTET GYNECOL 1990;163:1323-33.)

Key words: Mg^{++}, calcium channel blocker, uteroplacental vessels, preeclampsia, thromboxane A_2

Increased peripheral vascular resistance and blood pressure with impaired uteroplacental blood flow are main characteristics of preeclampsia.[1, 2] These changes have been explained by imbalance in the synthesis pattern of prostacyclin and thromboxane A_2 (TxA_2). Although the role of prostacyclin has been questioned by results from infusion studies in vivo,[3] placental tissues show increased capacity to produce TxA_2,[4] which could account for the increased vascular resistance. Analogues of TxA_2 produce vasoconstriction in fetal placental vessels,[5] but the effects on the maternal uteroplacental vessels and the possibilities of interference with such responses are not known.

Magnesium is currently used in the treatment of preeclampsia, and the ion produces relaxation of various peripheral vessels,[6] including the fetal umbilical and stem villous arteries.[7, 8] The mechanisms involved in these responses seem to include interference with transmembrane Ca^{++} influx[6, 8] but may include enhanced endothelial production of prostacyclin as well.[9] Calcium channel blockers of the dihydropyridine group show antihypertensive effects in patients wtih preeclampsia,[10, 11] and these drugs produce relaxation of isolated uteroplacental arteries.[12] The effects of Mg^{++} and dihydropyridine calcium channel blockers on contractile activation induced by TxA_2 do not seem to have been studied in maternal and fetal uteroplacental arteries.

In this study we have tested the effects of the stable TxA_2 analog U46619 on isolated, small human uteroplacental arteries from term pregnant patients. The responses have been compared with those produced by norepinephrine and vasopressin in maternal vessels and those produced by prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) in

fetal vessels. Moreover, we have studied the effects of Mg^{++} and isradipine on U46619-induced contractile activation in both types of vessel.

Material and methods

After informed, written consent was obtained, myometrial biopsy specimens were taken from the upper edge of the isthmic incision at term cesarean section because of genital herpes ($n = 2$), previous cesarean section ($n = 2$), or breech presentation ($n = 4$). In addition, macroscopically normal cotyledons were excised together with adjacent chorionic plate. All specimens were immediately placed in ice-cold Krebs solution and transported to the laboratory. By careful dissection under a stereomicroscope, stem villous arteries (inner diameter 300 to 400 μm) were identified in the cotyledons, and intramyometrial arteries (inner diameter 300 to 500 μm) were exposed in the myometrial biopsy specimens. The vessels were prepared as vascular rings (length 1.0 to 1.2 mm), and the preparations were then mounted in 5 ml organ baths containing Krebs solution (37.0° ± 0.5° C) bubbled with carbogen (95% oxygen and 5% carbon dioxide). The final pH was 7.40 ± 0.05. The short parallel legs of two L-shaped hooks were carefully inserted through the lumina of the vessels.[13] One of these hooks was attached to a displacement device that allowed fine adjustments of tension, and the other was connected to a Grass Ft 03 transducer. Isometric tension was recorded and displayed on a Beckmann R 611 polygraph.

The preparations were allowed to equilibrate for 1 hour. During this period passive tension was adjusted to 4 mN in the intramyometrial vessels and to 3 mN in the stem villous arteries. These resting tension levels were shown to be near optimum for contractile responses to depolarization with K^+ (124 mmol/L). After the equilibration period, contractions were repeatedly induced by K^+ (124 mmol/L) until reproducible (<10% variation between two successive contractions). Subsequent contractile responses were expressed as a percent of the mean of the last two of the initial K^+-induced contractions. The integrity of the endothelium was regularly controlled by testing the relaxant effects of substance P 10^{-7} mol/L in vessels precontracted by norepinephrine 10^{-5} mol/L (maternal vessels) or $PGF_{2\alpha}$ 10^{-5} mol/L. Only preparations showing more than 80% relaxation were used for further experiments. By contrast, in fetal and maternal vessels that were denuded of endothelial lining by gently moving a hair through the lumen, substance P induced <15% relaxation.

The relaxant effects of Mg^{++} and isradipine on U46619-induced tension were calculated by computerized planimetry during the 10-minute period subsequent to addition of the substance and expressed as a percentage of the area under the U46619-induced contraction 10 minutes before addition of the relaxing substances. Solvent-treated preparations contracted by U46619 served as controls.

Concentration-response relations to U46619, norepinephrine, vasopressin, and Ca^{++} were characterized by the maximum amplitude achieved (E_{max} in percent of initial K^+ response) and the concentration producing half-maximum response (EC_{50}). EC_{50} values were expressed as $pD_2 = -\log(EC_{50})$. Mean and SE for E_{max} and pD_2 were determined. After homogeneity of variance was ascertained, significance of difference was assessed by one-way analysis of variance or, if appropriate, by the two-tailed t test for groups of nonpaired observations with a level of significance of 0.05.

Solutions. Normal Krebs solution: sodium chloride, 119 mmol/L; potassium chloride, 4.6 mmol/L; sodium bicarbonate, 15 mmol/L; calcium chloride, 1.5 mmol/L; magnesium chloride, 1.2 mmol/L; sodium phosphate, 1.2 mmol/L; glucose, 11 mmol/L. High-K^+ Krebs solution: potassium chloride, 124 mmol/L; sodium bicarbonate, 15 mmol/L; calcium chloride, 1.5 mmol/L; magnesium chloride, 1.5 mmol/L; sodium phosphate, 1.2 mmol/L; glucose, 11 mmol/L. In Ca^{++}-free solutions calcium chloride was omitted and ethylene glycol-bis(β-aminoethyl ether)N,N,N′,N′-tetraacetic acid (EGTA) 0.01 mmol/L was added.

Drugs. Drugs used were as follows: U46619 [(15S)-hydroxy-11α,9α-(epoxymethano)prosta-5Z,13E-dienoic acid (Upjohn), isradipine (Sandoz), NA [(−)-norepinephrine, Sigma Chemical Co.], vasopressin (arginine vasopressin, Sigma), and $PGF_{2\alpha}$ (Dinoprost, Upjohn).

Results

Neither the maternal intramyometrial preparation nor the fetal stem villous arterial preparation exhibited spontaneous contractile activity. In maternal arteries K^+ (124 mmol/L) depolarization induced an initial fast rise in tension that developed into a tonic contraction with higher amplitude. The maximum tension reached was 10 ± 1 mN/mm ($n = 8$).

In the fetal vessels the initial rapid phase continued into a maintained contraction with lower amplitude within 1 to 2 minutes. The maximum amplitude was 10 ± 2 mN/mm ($n = 8$). The corresponding tension level reached during the second phase was 90% of the initial maximum amplitude.

Effects of U46619, norepinephrine, and vasopressin. U46619 10^{-10} to 10^{-6} mol/L, norepinephrine 10^{-8} to 10^{-4} mol/L, and vasopressin 10^{-11} to 10^{-8} mol/L all induced concentration-related contractile responses in the maternal intramyometrial vessels (Fig. 1). However, the shape of the concentration-response curves for

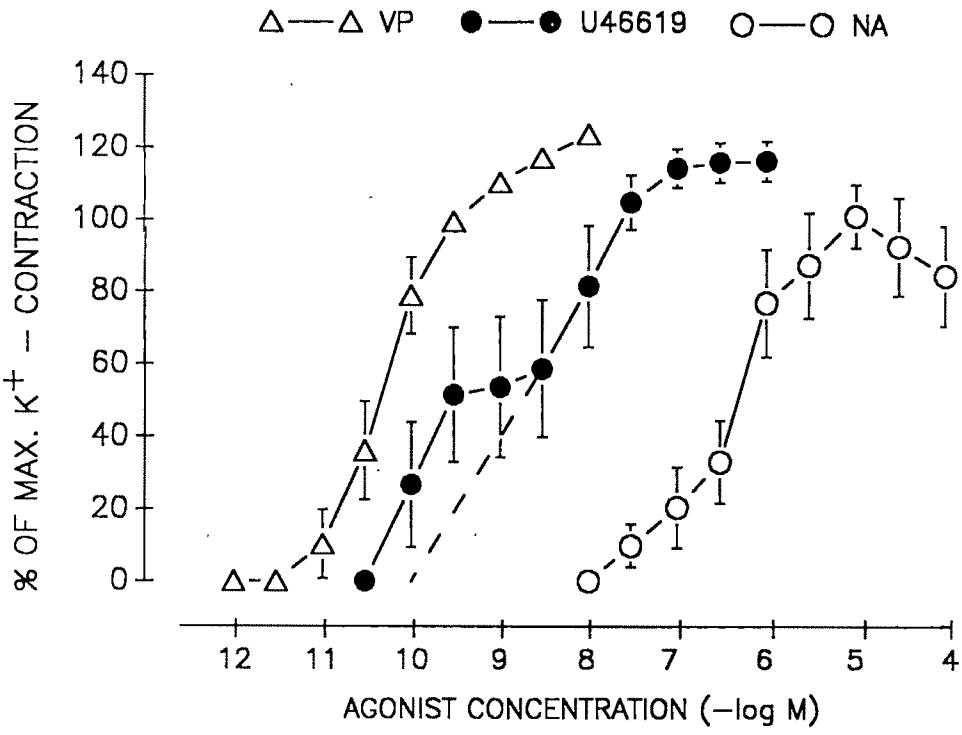

Fig. 1. Maternal intramyometrial arteries. Concentration-response relations for vasopressin *(VP)* 10^{-11} to 10^{-8} mol/L, U46619 10^{-10} to 10^{-6} mol/L, and NA *(NA)* 10^{-8} to 10^{-4} mol/L. Each point represents the mean of eight experiments. *Vertical bars* denote SE, when this exceeded the size of the symbols. The *dotted line* represents the linear extension of the latter part of the U46619 concentration-response curve, which was sued for calculation of the pD_2 value for that part of the U46619 response. See text for further details.

these agonists differed. Thus cumulative addition of U46619 produced a biphasic concentration-response curve. A plateau at about 50% of the K^+ response was achieved in the U46619 concentration range of 3×10^{-10} mol/L. The first part of the concentration-response curve had an apparent E_{max} of about 54% of the K^+ response with a corresponding pD_2 value of 9.6 ± 0.2. At further addition of U46619 a final E_{max} of 116% ± 6% of the K^+ response was reached. A pD_2 value of 8.5 ± 0.6 for this part of the curve was assessed by extrapolation of the linear part of the concentration-response curve (corresponding to U46619 3×10^{-9} to 3×10^{-8} mol/L) (Fig. 1). By contrast norepinephrine and vasopressin produced sigmoid concentration-response curves with a linear course corresponding to the EC_{50} value. E_{max} values of vasopressin- and norepinephrine-induced contractions were 124% ± 5% and 101% ± 9% of the initial K^+ response, respectively. The pD_2 values were 9.96 ± 0.30 and 6.28 ± 0.25, respectively.

In the stem villous arteries U46619 and $PGF_{2\alpha}$ induced concentration-related responses (Fig. 2). In these vessels U46619 produced sigmoid concentration-response curves parallel to the concentration-response curve of $PGF_{2\alpha}$. E_{max} values for U46619 and $PGF_{2\alpha}$ responses were 145% ± 9% and 139% ± 4.4% of the initial K^+ contraction, respectively. The pD_2 values were 8.53 ± 0.01 and 5.93 ± 0.09, corresponding to EC_{50} values of 2.9×10^{-9} and 1.2×10^{-6} mol/L, respectively. As previously shown norepinephine and vasopressin did not induce contractile responses in the fetal stem villous arteries.[14, 15]

Effects of Mg^{++} and isradipine on U46619-induced contractions. Responses to U46619 10^{-7} mol/L were close to maximum (Fig. 1) in intramyometrial preparations. The responses consisted of an initial fast rise in tension, which continued into a maintained contraction with minor fluctuations in tension (Fig. 3). Tension produced by lower concentrations of the compound was characterized by major fluctuations. In the stem villous vessels U46619 10^{-8} mol/L induced a near-maximum response amounting to 120% ± 5% of the initial K^+ contraction (Fig. 2).

At prolonged exposure to U46619 the tension induced was inconstant. To evaluate the effects of Mg^{++} and isradipine on U46619-induced tension the prep-

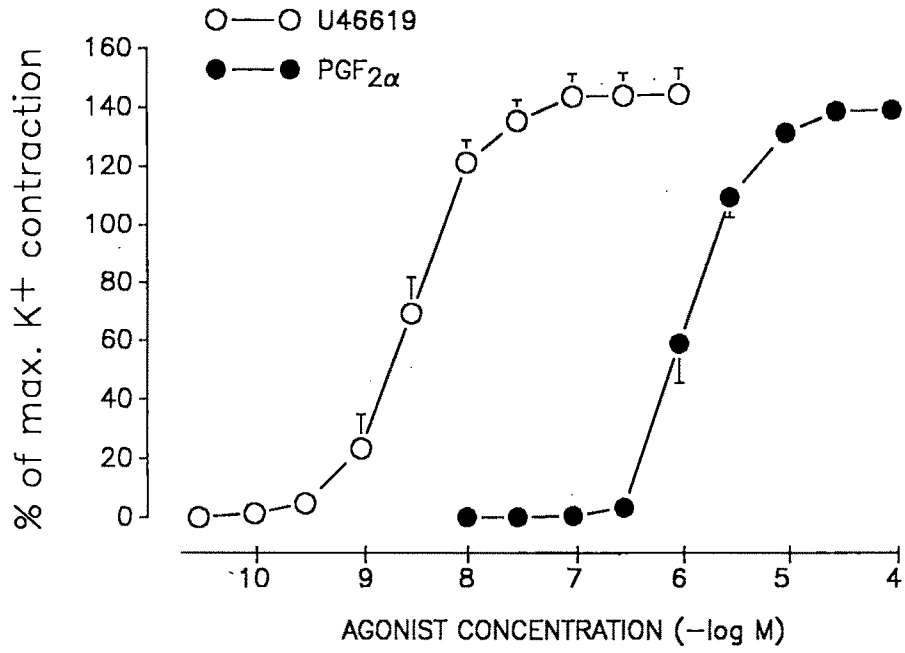

Fig. 2. Fetal stem villous arteries. Concentration-response relations for U46619 10^{-10} to 10^{-6} mol/L and $PGF_{2\alpha}$ 10^{-8} to 10^{-4} mol/L. Each point represents the mean of eight experiments. *Vertical bars* denote SE, when this exceeded the size of the symbols.

arations were exposed to Mg^{++} 0.5 mmol/L and precontracted by U46619 10^{-7} mol/L (maternal vessels) or 10^{-8} mol/L (fetal vessels). The relaxant effects of Mg^{++} or isradipine were then tested by addition of single concentrations of these agents in separate preparations. In maternal preparations Mg^{++} 1.0 to 6.0 mmol/L produced concentration-dependent relaxation of tension induced by U46619 10^{-7} mol/L by up to 43%, and significant relaxation as related to control preparations was obtained at a Mg^{++} concentration of 1.0 mmol/L. In the fetal arteries the relaxant properties of Mg^{++} on U46619-induced contractions were less pronounced than in maternal vessels and significant relaxation appeared at a Mg^{++} concentration of 1.5 mmol/L (Fig. 4, *A*).

Isradipine produced similar concentration-dependent relaxation of U46619-induced tension by up to 33% in both maternal and fetal vessels. Significant relaxation as related to control preparations was obtained after addition of isradipine 10^{-10} mol/L (Fig. 4, *B*). In preparations precontracted by U46619 10^{-7} or 10^{-8} mol/L and exposed to isradipine 10^{-6} mol/L, addition of Mg^{++} 6.0 mmol/L consistently produced further relaxation (Fig. 3).

Effects of endothelial disruption, indomethacin, and digoxin on responses to Mg^{++} and isradipine. Removal of the endothelium or pretreatment with indomethacin 10^{-6} mol/L or digoxin 10^{-6} mol/L did not influence the inhibition produced by Mg^{++} or isradipine on tension produced by U46619 10^{-7} mol/L in maternal intramyometrial arteries or 10^{-8} mol/L in the fetal stem villous arteries.

Effects of Mg^{++} and isradipine on responses to Ca^{++}. The vessels were exposed to Ca^{++}-free medium (EGTA 0.01 mmol/L) for 30 minutes (repeated washing during the initial 15 minutes), and responses to K^+ 124 mmol/L or U46619 (10^{-7} mol/L in maternal vessels and 10^{-8} mol/L in fetal vessels) were elicited after preincubation for 20 minutes with Mg^{++} 6.0 mmol/L, with isradipine 10^{-6} mol/L (Mg^{++} 0.5 mmol/L) or in controls (Mg^{++} 0.5 mmol/L). The development of constant tension was awaited and Ca^{++} was then added cumulatively.

Responses in Ca^{++}-free medium. In Ca^{++}-free medium (EGTA 0.01 mmol/L) responses to K^+ 124 mmol/L were abolished in both types of vessel (Fig. 5, *A* and *B*).

Responses to U46619 (10^{-7} mol/L) in Ca^{++}-free medium in maternal vessels consisted of an initial tension peak, which reached 56% ± 9% (n = 8) of the initial K^+ response. These continued into a lower tension level of about 44% ± 8% (n = 8). In vessels pretreated with Mg^{++} 6.0 mmol/L the response to U46619 was reduced to 45% and 18%, respectively. Isradipine reduced

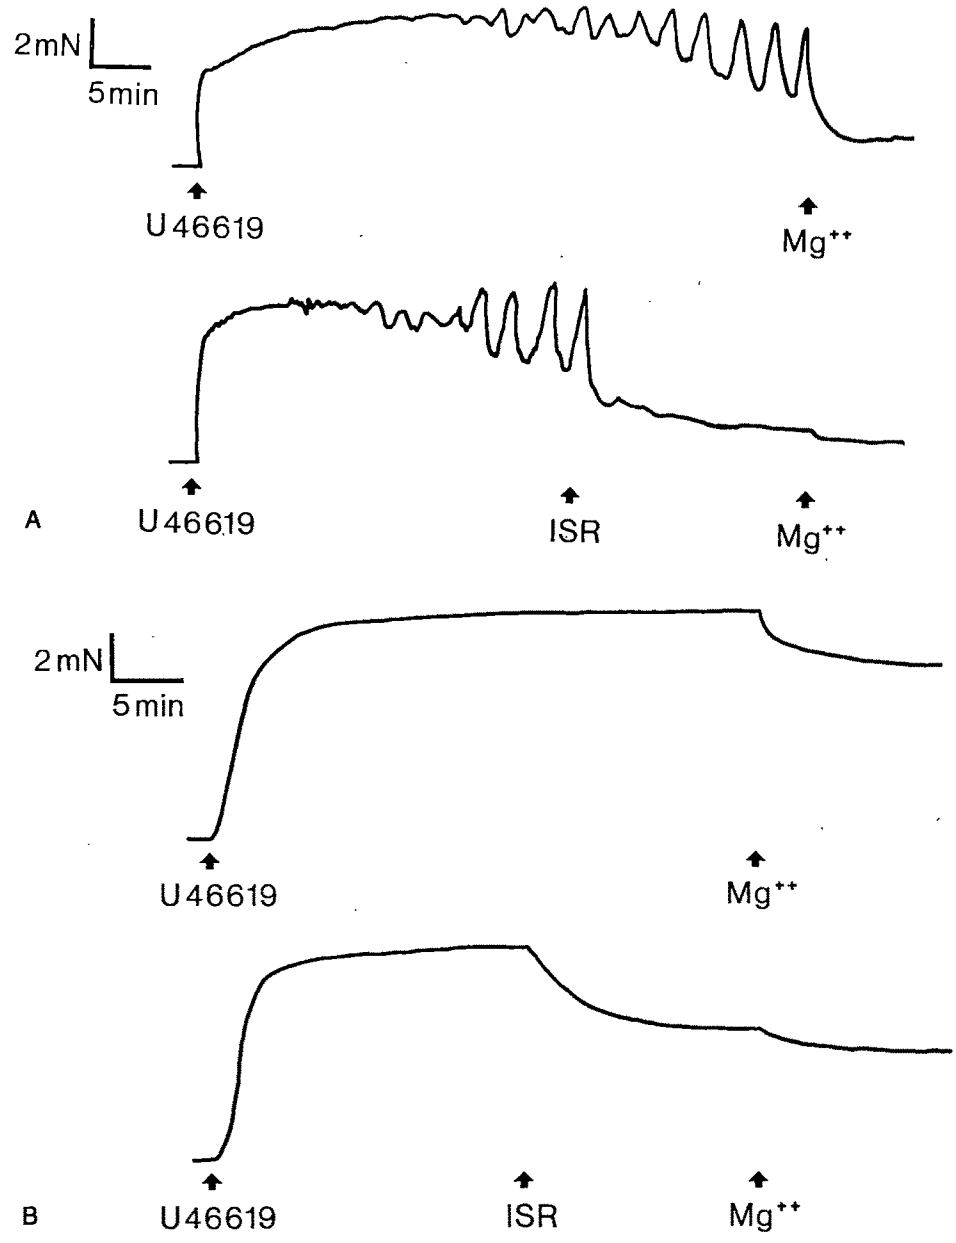

Fig. 3. Maternal intramyometrial arteries **(A)** and fetal stem villous arteries **(B)**: Response to U46619 10^{-7} mol/L (maternal vessels) and 10^{-8} mol/L (fetal vessels) and effects of isradipine *(ISR)* 10^{-6} mol/L and Mg^{++} 6.0 mmol/L.

the response to 40% and 16%, respectively (Fig. 6, *A*).

In fetal vessels U46619 (10^{-8} mol/L) produced a fast rise in tension, which was maintained until the subsequent Ca^{++} addition. The response in Ca^{++}-free medium was reduced from 140% to 35% (n = 8) of the initial K^+ response as compared with the response in normal Krebs solution. Pretreatment with Mg^{++} or isradipine did not cause any further reduction of the U46619 response (Fig. 6, *B*).

Responses to Ca^{++} after K^+ stimulation. The responses produced by addition of Ca^{++} (0.01 to 4.0 mmol/L) after initial stimulation with K^+ (124 mmol/L) in Ca^{++}-free medium were partially depressed by Mg^{++} 6.0 mmol/L. In the maternal intramyometrial arteries the E_{max} and pD_2 values were significantly reduced (Fig. 5, *A*). In stem villous arteries the pD_2 and E_{max} values could not be calculated, since no definite maximum was achieved at Ca^{++} 4.0

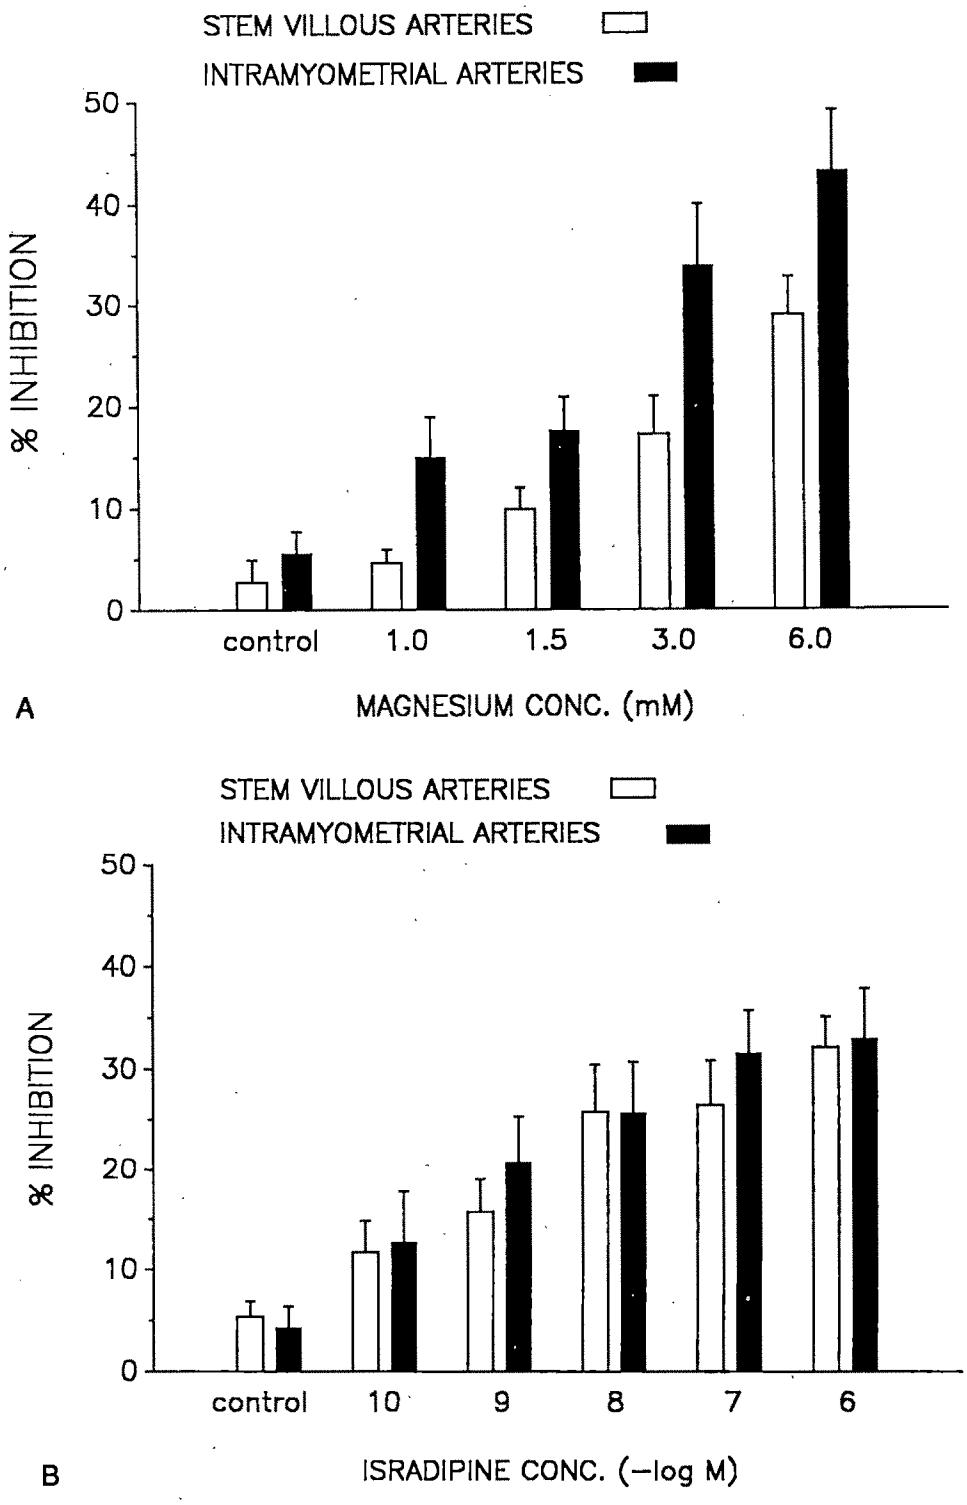

Fig. 4. Maternal intramyometrial arteries and fetal stem villous arteries. Concentration-response relations for Mg^{++} 1.0 to 6.0 mmol/L **(A)** and isradipine 10^{-10} to 10^{-6} mol/L **(B)** in vessels pretreated with U46619 10^{-7} mol/L (maternal vessels) or 10^{-8} mol/L (fetal vessels). Single exposures of Mg^{++} and isradipine in separate preparations were used for these experiments ($n = 8$). *Vertical bars* denote SE.

mmol/L. However, the tension induced by Ca^{++} 0.1 to 0.5 mmol/L was reduced by Mg^{++} as compared with the responses in the control preparation (Fig. 5, *B*), while responses to Ca^{++} 1.0 to 4.0 mmol/L showed no significant decrease.

In both maternal and fetal vessels pretreated with isradipine 10^{-6} mol/L the responses to readdition of Ca^{++} (0.01 to 4. mmol/L) were virtually abolished (Fig. 5, *A* and *B*).

Responses to Ca^{++} after U46619 stimulation. In maternal preparations Mg^{++} 6.0 mmol/L produced partial inhibition of the response to subsequent addition of Ca^{++} (0.01 to 4.0 mmol/L), as compared with preparations exposed to Mg^{++} 0.5 mmol/L. In vessels pretreated with isradipine 10^{-6} mol/L (Mg^{++} 0.5 mmol/L) responses to Ca^{++} (0.01 to 4.0 mmol/L) were even more reduced (Fig. 6, *A*). However, the inhibition of responses to Ca^{++} produced by isradipine 10^{-6} mol/L and Mg^{++} 6.0 mmol/L did not differ significantly.

In fetal stem villous arteries Mg^{++} (6.0 mmol/L) and isradipine (10^{-6} mol/L) produced a similar inhibition of the responses to Ca^{++} 0.01 to 4.0 mmol/L (Fig. 6, *B*).

Comment

The TxA_2 analog U46619 is a potent vasoconstrictor of umbilical and placental vessels as shown in vitro on human preparations[5, 16, 17] and in animal in vivo experiments.[3] In accordance with previous studies the present results showed that U46619 produced concentration-dependent vasoconstriction in isolated human uteroplacental arteries. Lower levels of U46619 were needed to produce significant contraction of maternal arteries as compared with fetal arteries. Furthermore, the concentration-response curves showed different profiles in maternal and fetal vessels showing a biphasic course in the intramyometrial arteries. Similar pD_2 values were assessed for fetal vessels and for the late part of the concentration-response curve in the maternal vessels, while a significantly higher pD_2 value was estimated for the first part of the concentration-response curve in the maternal vessels. It cannot be excluded that these results reflect the existence of two subtypes of TxA_2 receptors in the maternal intramyometrial vessels. Further studies including specific receptor antagonists are needed to clarify this possibility.

In preeclampsia there seems to be an imbalance in the synthesis ratio between prostacyclin and TXA_2, TXA_2 being produced in excess.[4] However, it has been shown that preeclampsia is not accompanied by changes in TXA_2 production that can be detected in maternal blood.[18] On the other hand, an increased production of TXA_2 was found in placentas from hypertensive pregnancies,[19] suggesting that a local disturbance in TXA_2/PGI_2 balance could be responsible for the increased resistance in the uteroplacental vascular bed. Together with those of others, our results strengthen the hypothesis that TXA_2 is partly responsible for the vasospasm in uteroplacental vessels, which is a constant feature in the syndrome of preeclampsia.[2]

The effects of Mg^{++} on the uteroplacental resistance vessels have recently been evaluated,[8] and it has been demonstrated that Mg^{++} relaxes vessels, which is important for resistance regulation in the human uteroplacental vascular bed. In this in vitro study Mg^{++} in concentrations that are readily reached during therapeutic use[20] effectively relaxed U46619-induced contractions as compared with responses in control preparations exposed to 0.5 mmol/L Mg^{++}. In late pregnancy the concentrations of Mg^{++} in plasma range from 0.5 to 0.8 mmol/L (median about 0.65 mmol/L, $n = 2000$) (Skajaa K. Unpublished observations), with subsequent free extracellular Mg^{++} of about 0.5 mmol/L.

Mg^{++} seems to inhibit transmembrane calcium influx,[6, 8] but several intracellular mechanisms involved in the activation of vascular contraction may be influenced by the ion.[6, 21-23] These results give further support to the view that Mg^{++} inhibits Ca^{++} influx through voltage-operated channels, since the K^+-induced contractions were reduced. Responses to U46619 and other prostanoids seem to be mediated by an increase in intracellular Ca^{++} brought about partly by a transmembrane Ca influx via receptor-operated channels and partly by a release of Ca from intracellular stores.[24] The response to U46619 in this study and to $PGF_{2\alpha}$ as shown previously[8] were partly inhibited by Mg^{++}, as were the responses to Ca^{++} after stimulation with U46619 in calcium-free medium. Thus Mg^{++} may interfere with Ca^{++} entry through receptor-operated channels, as well as with Ca^{++} release from intracellular stores.[21] However, the exact mechanisms by which Mg^{++} exerts its inhibitory effects are still unclear.

Calcium antagonists of the dihydropyridine type have a common action to inhibit Ca^{++} influx into smooth muscle cells and subsequent contraction. The dihydropyridine receptor is a component of the voltage-dependent calcium channels,[25, 26] which explains the effective blockade of Ca^{++} entry through these channels by the dihydropyridine calcium antagonists. Although this is the primary site of action of calcium antagonist, some other sites of action cannot be excluded. In this study it clearly emerged that isradipine very effectively hindered the Ca^{++} influx through voltage-operated Ca channels as the response

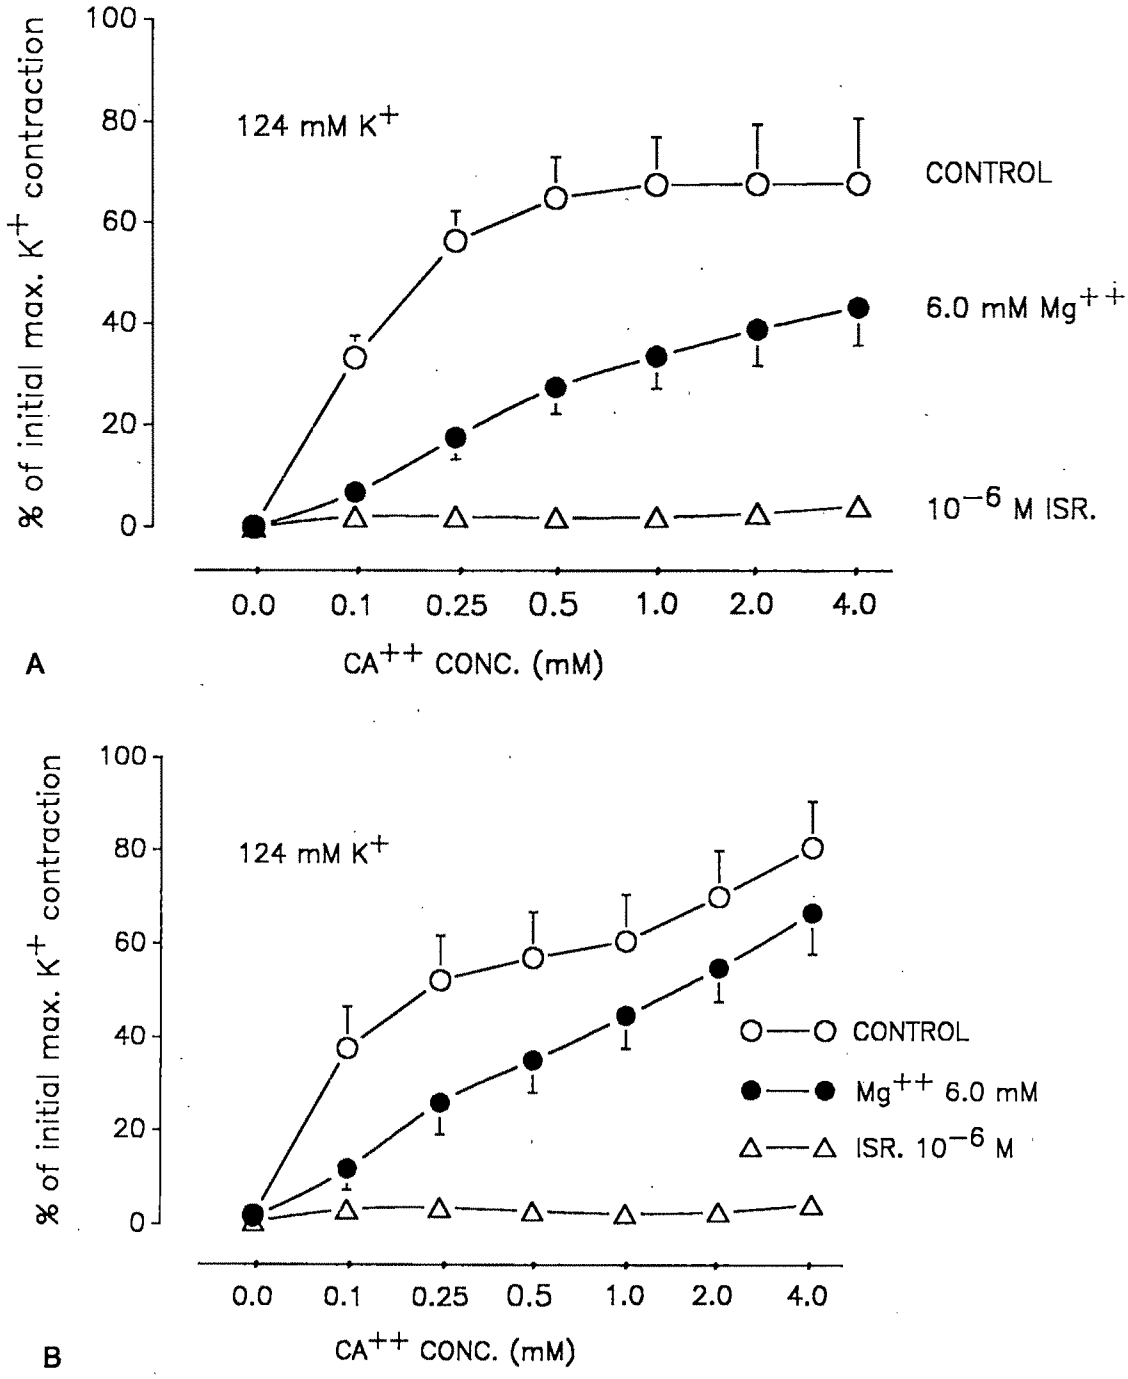

Fig. 5. Maternal intramyometrial arteries (**A**) and fetal stem villous arteries (**B**) preincubated in Ca^{++}-free medium. Concentration-response relations for Ca^{++} 0.1 to 4.0 mmol/L in vessels exposed to isradipine *(ISR)*. 10^{-6} mol/L or Mg^{++} 6.0 mmol/L after initial depolarization with K^+ 124 mmol/L. to high K^+ concentration was completely abolished. However, the fact that the U46619 response in Ca^{++}-free medium was reduced by isradipine suggests other actions of isradipine as well.

In this study the effects of Mg^{++} and isradipine were similar although isradipine was more effective with respect to inhibition of Ca^{++} influx as reflected by effects on K^+-induced contractile activation. However, Mg^{++} induced a further relaxation in preparations precontracted with U46619 and then exposed to isradipine 10^{-6} mol/L, i.e., producing maximum (maternal vessels) or near-maximum (fetal vessels) inhibition. This could reflect that Mg^{++} interfered with membrane and/or other cellular mechanisms[21, 22] that are unaf-

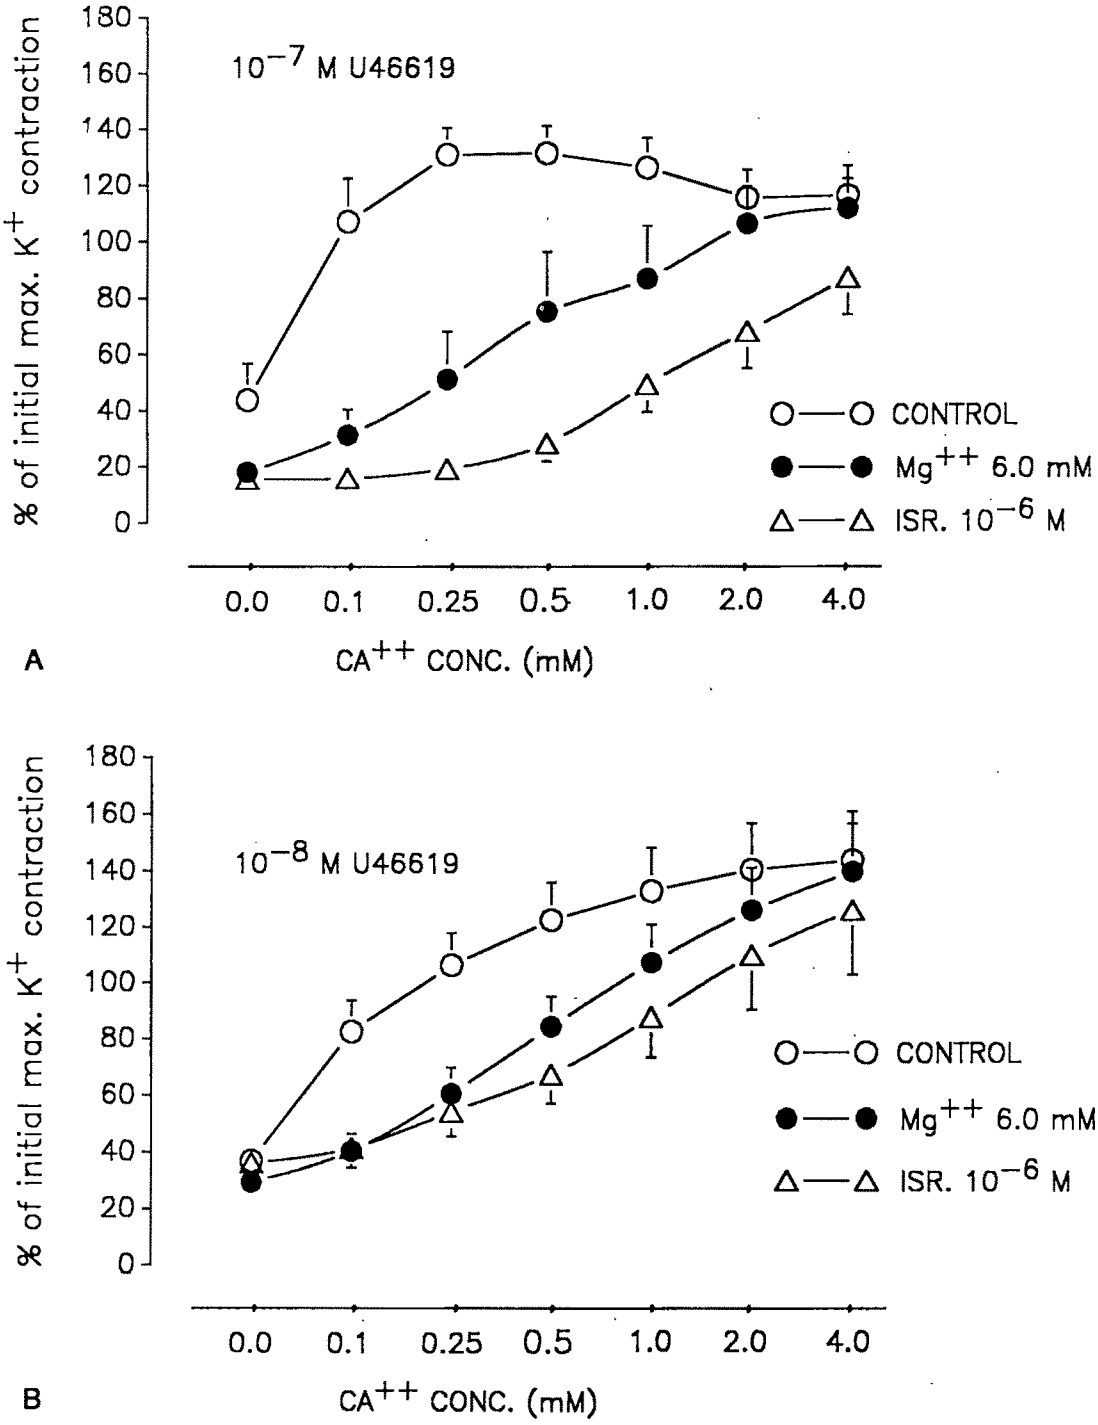

Fig. 6. Maternal intramyometrial arteries (**A**) and fetal stem villous arteries (**B**) preincubated in Ca^{++}-free medium. Concentration-response relations for Ca^{++} 0.1 to 4.0 mmol/L in vessels exposed to isradipine *(ISR)*. 10^{-6} mol/L or Mg^{++} 6.0 mmol/L after initial stimulation with U46619 10^{-7} mol/L (maternal vessels) or 10^{-8} mol/L (fetal vessels). In the maternal vessels the response to U46619 in Ca-free medium consisted of an initial peak, which continued into a lower tension level (see text). Only the lower tension level of the response is shown in the figure. Each point represents the mean of eight experiments. *Vertical bars* denote SE, when this exceeded the size of the symbols.

fected by dihydropyridine calcium antagonists such as isradipine. However, other explanations are possible. Thus isradipine may have changed the calcium channel sensitivity to Mg^{++}.

If treatment of preeclampsia is required, improvement of uterine and placental blood flow is crucial, particularly as the systemic hypertension may be considered a consequence rather than the cause of the

disease.[2] The relation between fetal and maternal uteroplacental vascular effects of Mg^{++} is therefore of considerable clinical interest. Apparently, the effects of increasing concentrations of Mg^{++} include relaxation of both fetal and maternal uteroplacental arteries, but the effects were more pronounced in the maternal vessels. In addition Mg^{++} produces relaxation of the myometrium,[27, 28] and, together with the preference of the maternal vasculature, this could be of advantage in the treatment of preeclampsia. However, the hemodynamic effects of such treatment depend on the overall systemic response. In the pregnant rabbit Mg^{++} infusion increased uterine blood flow.[29] Similar studies on uteroplacental blood flow in human pregnancies are sparse, but Mg^{++} infusion in human volunteers has been shown to reduce the systemic blood pressure concomitant with a significant increase in renal blood flow and in excretion of prostacyclin metabolites.[30] Moreover, Mg^{++} in therapeutic concentrations mediates enhanced production of prostacyclin by cultured human umbilical vein endothelial cells.[9] Thus it seems that Mg^{++} in vivo may alleviate the action of TxA_2 in several respects. However, enhanced prostacyclin production does not seem of importance for the relaxant responses to Mg^{++} in isolated human uteroplacental arteries since no effects of indomethacin or of endothelial removal were found. The relaxant effects of Mg^{++} did not seem to be mediated by a stimulation of the sodium-potassium-adenosine triphosphatase, since pretreatment with digoxin, which inhibits this enzyme, did not influence the action of Mg^{++} on U46619-induced contractions.

In conclusion, our results show that Mg^{++} and the calcium antagonist isradipine inhibit contraction produced by TxA_2 in uteroplacental resistance vessels. If preeclampsia-eclampsia involves increased vascular actions of TxA_2, these data give support to the established use of magnesium sulfate in the treatment of these conditions and suggest that calcium antagonists may be of potential benefit.

We thank Ms. Kirsten Aggerholm for skilled technical assistance.

The use of in situ hybridization to show human papillomavirus deoxyribonucleic acid in metastatic cancer cells within lymph nodes

George Lewandowski, MD, Gregorio Delgado, MD, Robert W. Holloway, MD, Michael Farrell, PhD, A. Bennett Jenson, MD, and Wayne D. Lancaster, PhD
Washington, D.C.

Southern blot hybridization has been used to identify human papillomavirus types in both primary tumors and lymph node metastases. However, this technique requires fresh-frozen tissue and is incapable of localizing deoxyribonucleic acid sequences to specific cell types in the tumor sample. In contrast, in situ hybridization precisely locates viral sequences within tumor cells while preserving cellular architecture. Further, in situ hybridization requires only small samples of formalin-fixed, paraffin-embedded tissues. Five lymph nodes (from four patients) containing metastatic cervical squamous tumor cells (identified with hematoxylin and eosinophil staining) were analyzed with in situ hybridization techniques with human papillomavirus type 16 deoxyribonucleic acid probes labeled with sulfur 35. The primary cervical cancer from all four patients had been shown to contain human papillomavirus type 16 sequences by Southern blot. Three specimens from two patients clearly showed the presence of human papillomavirus type 16 sequences within the nuclei of metastatic tumor cells, whereas two specimens were nondiagnostic most likely as a result of the small volume of cancer relative to the size of the lymph node. This information indicates that it is the tumor cells themselves that contain viral deoxyribonucleic acid and provides additional evidence linking human papillomavirus with cervical carcinogenesis. (Am J Obstet Gynecol 1990;163:1333-7.)

Key words: Human papillomavirus infection, metastatic cervical cancer, in situ hybridization

Preinvasive and invasive lower genital neoplasms have been broadly linked to a sexually transmissable agent with a number of etiologic factors presented by LaVecchia et al.[1] Early work by Meisels et al.[2] showed koilocytic atypia, which is pathognomonic for human papillomavirus (HPV) infection, in 70% of patients with cervical dysplasia. Kurman et al.,[3] Syrjanen,[4] Walker et al.,[5] and others used the immunoperoxidase technique to show specific papillomavirus antigens in cervical and vulvar lesions, but found that lesions which were less well differentiated did not retain the capability to synthesize capsid proteins into virions and therefore were not detectable by this technique. An additional drawback to our understanding of the relationship between HPV infection and oncogenesis has been the inability to grow HPV in cell culture. As a result, further definition of the role of HPV infection in carcinogenesis has relied on refinements in the techniques of molecular biology.

Southern blot hybridization[6] tissue typing of fresh or frozen tissue has been the "gold standard" method of

HPV detection, and has been used in the majority of reports dealing with HPV-related disease. A number of prospective studies[7-11] showed that HPV types 6 and 11 carry a low risk for progression to dysplasia and neoplasia, whereas HPV types 16, 18, 31, 33, and 35 are associated with many invasive lesions and seem to constitute a higher risk group.

Lancaster et al.[12] and Fuchs et al.[13] provided novel evidence in support of this association with the demonstration of the same HPV type in both primary tumors and their lymph node metastases, thus further implicating HPV in carcinogenesis. However, because this work was performed with the Southern blot hybridization technique, it was impossible to show with certainty whether the HPV deoxyribonucleic acid (DNA) was within actual tumor cells, or whether it merely existed within adjacent lymphocytes or lymphatic stroma.

To address this issue, in situ hybridization was developed to provide HPV typing information while preserving cellular architecture. The specific goal of this work was to show the presence of HPV type 16 DNA sequences in tumor cells within metastatic lymph nodes.

Material and methods

Source and handling of tissue. Tissues obtained from lymph node specimens of patients undergoing surgery for cervical malignancies at Georgetown University Hospital were analyzed with the use of frozen section. If tumor involvement was shown, a segment of the lymph node was obtained, frozen on dry ice, and stored at −70° C. The corresponding paraffin blocks that contained tumor-bearing lymphatic tissue were obtained from the Department of Pathology in each case in which frozen tissue was secured.

Southern blot hybridization. The frozen specimens described above were analyzed for the presence of HPV types 6/11, 16, and 18 by Southern blot hybridization.[6] HPV DNA probes radiolabeled with phosphorus 32 were prepared by nick translation with *Escherichia coli* DNA polymerase I. Blot transfer and hybridization were performed under moderately stringent conditions detailed elsewhere.[13]

In situ hybridization. Histologic analysis was done to confirm the presence of tumor in the paraffin-embedded lymph node section obtained. Adjacent serial sections 4 to 6 μm thick were mounted on slides that had been acid-cleaned and treated with poly-L-lysine solution.

HPV 6 and HPV 16 genomes were isolated from molecular clones described previously.[14] Viral DNA was released from the pBR322 vector by digestion with Bam HI and isolated by agarose gel electrophoresis and electroelution.

The HPV types 6 and 16 DNA fragments obtained were radiolabeled with ^{35}S deoxyadenosine triphosphate (New England Nuclear, Boston) with the "oligolabeling" technique of Feinberg and Vogelstein.[15] The specific activity of the probes determined with scintillation counting was found to range from 1.8 to 2.1×10^7 counts per minute per microgram of DNA. Radioactive probe fragments were separated from unincorporated nucleotide with a commercially available exchange resin (Nensorb, New England Nuclear) and concentrated with ethanol precipitation.

In situ hybridization analyses were performed on the tumor metastases as described by Brahic and Haase[16] and Gupta et al.[17] with the following modifications. After removal of paraffin and the initial dehydration, the tissue sections were incubated in 1 μg/ml proteinase K in phosphate-buffered saline solution for 20 minutes. With 25 to 30 μl of hybridization mixture (50% deionized formamide, 10% dextran sulfate, 0.6 mol/L sodium chloride, 0.01 mol/L Tris hydrochloride (pH 7.4), 0.5 mmol/L ethylenediaminetetraacetic acid, 1 mg/ml bovine serum albumin, 0.02% Ficoll, 0.02% polyvinylpyrrolidone, 0.2 mg/ml salmon sperm DNA, 0.5 mM dithiothreitol and 0.2 μg/ml of HPV type 6 or 16 DNA probes labeled with ^{35}S, hybridizations were carried out for 50 to 60 hours at 37° C. After the hybridizations, slides were washed and dehydrated by the method described by Gupta et al.[17]

Autoradiography. After air drying, the slides were dipped in photographic emulsion (nuclear tract NTB-3, Kodak, Rochester, N.Y.) which had been melted and maintained at 45° C. Exposure was performed in desiccated, light-free containers for 5 to 7 days at 4° C. The emulsion was developed following manufacturer's recommendations, and slides were stained with hematoxylin before the coverslips were positioned.

Results

Five different lymph nodes containing metastatic cervical squamous cancer from four patients were analyzed. Two separate nodal specimens were studied from one patient, representing metastases from paraaortic and scalene lymph node biopsy specimens obtained 9 months apart. The primary tumor from each of the four patients had been found to contain HPV type 16 with the use of Southern blot hybridization. The Southern blot demonstration of HPV type 16 involvement in these cases has already been reported.[12]

Three nodal samples from two patients showed the presence of HPV type 16 DNA within nests of tumor cells in the lymph nodes. In no instance did the control HPV type 6 DNA hybridize to the samples. Fig. 1, *A* and 1, *B*, show low- and high-power magnifications of one of these specimens. The darkened areas of silver granule deposition indicate probe hybridization within the tumor metastases but not in the surrounding lym-

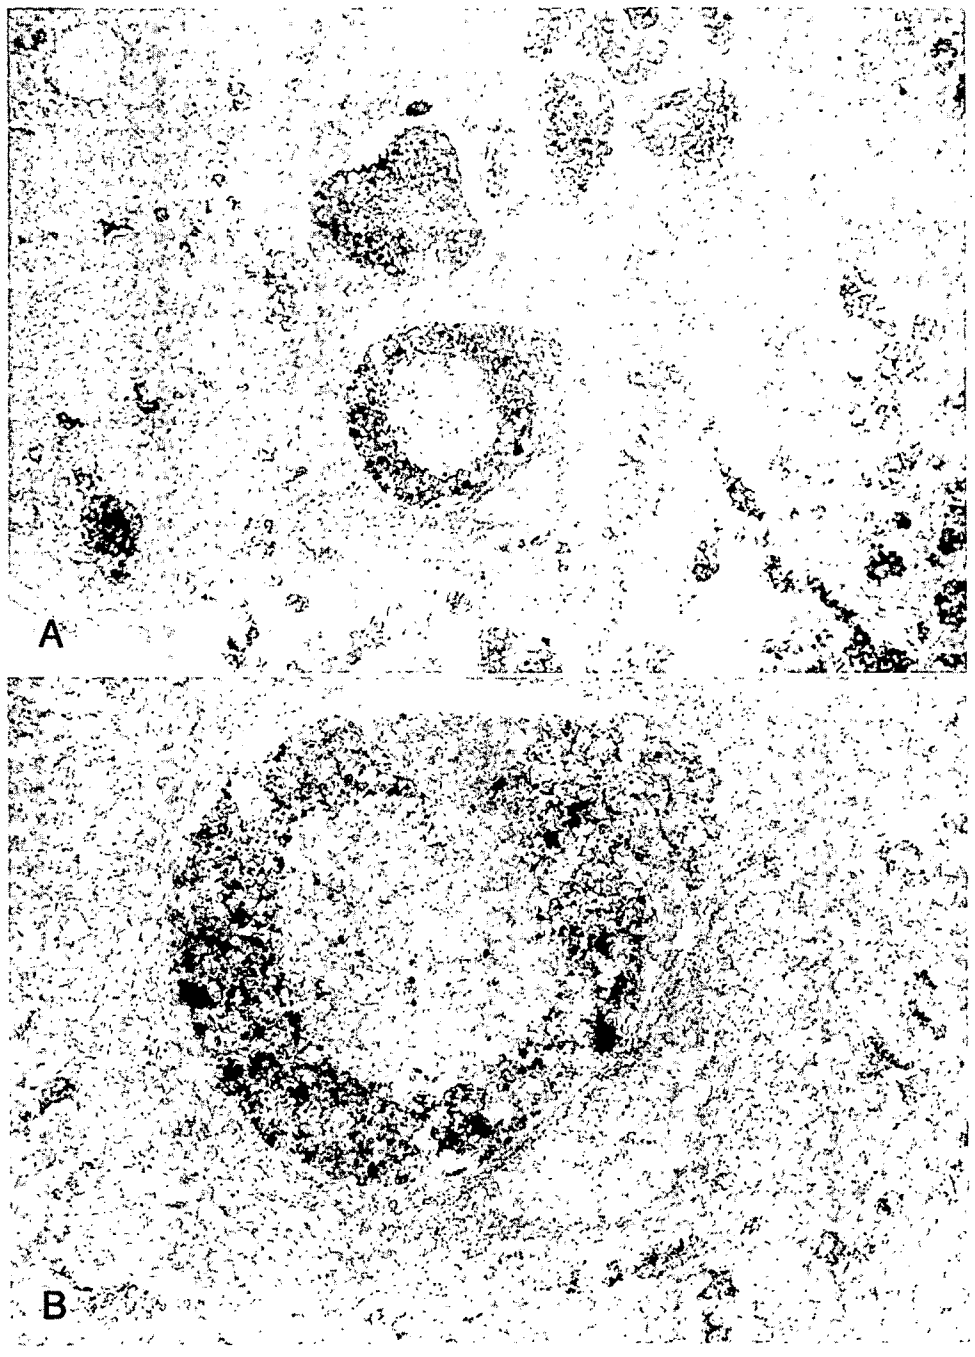

Fig. 1. In situ hybridization analysis with HPV type 16 DNA probe labeled with ^{35}S. **A,** Low-power magnification shows a concentration of black granules indicating positive reaction within tumor metastases. **B,** Note weak hybridization within central necrosis in high-power magnification.

phocytes or stroma. In the high-power magnification view (Fig. 1, *B*) a central area of necrosis within the metastatic nest shows low hybridization intensity corresponding to an area of nonviable cells that presumably contain degraded DNA. Assays of lymph nodes from the remaining two patients were suggestive of HPV type 16 involvement, showing weak probe hybridization. Unfortunately, the microscopic nature of tumor foci within these nodes and tissue loss from the slides kept us from declaring these specimens to be definitively positive for HPV type 16.

Comment

We have used in situ molecular hybridization to show the presence of HPV type 16 DNA within tumor metastases to lymph nodes. In situ hybridization largely

preserves cellular architecture. This allowed us to show that the viral genomes were within the tumor cells and not in the surrounding lymphocytes. Further, this evidence of the virus was found at sites distant from and noncontiguous to the primary lesion, the presumed site of viral entry into the system. This information answers an objection to our earlier use of Southern blot hybridization that showed HPV types in metastatic lymph nodes. It further pinpoints the HPV DNA to the tumor cells themselves.

Walboomers et al.[18] reported a single case in which in situ hybridization was used to indicate the presence of HPV type 16 in a fresh-frozen pelvic tumor metastasis from an endocervical adenocarcinoma. They found that the in situ hybridization positivity was roughly correlated to the copy number of the DNA within the metastasis. Nuovo and Richart[19] corroborate this information in their comparison of slot blot, Southern blot, and in situ hybridization, and added that cases with weak hybridization signals generally reflected less dysplastic lesions. Our demonstration of strong signals in hybridizations from separate lymph node tumor metastases suggests a possible clinical role for in situ hybridization that may ultimately offer a clue as to HPV-related tumor biology and prognosis.

In situ hybridization offers an additional advantage of using formalin-fixed, paraffin-embedded tissues for analysis. Duplicate examinations are therefore possible, which will allow for further testing should assay modifications or new HPV types be discovered. Only a single report has used Southern blotting on paraffin-embedded tissue,[20] and the technique requires special tissue handling that may not be applicable to standard surgical pathologic procedures.

However, in situ hybridization is not without drawbacks. We found in situ hybridization to be technically more difficult and as a result potentially less sensitive than Southern blotting. Individual assays may take from 2 weeks to several months depending on the specific activity of the probe and the condition and amount of viral DNA within the specimen. Caussey[21] found a 30% detection rate with in situ hybridization compared with rates between 70% and 89% for cervical cancers with the use of blot technology. Further investigation into HPV-related carcinogenesis will depend on information from both in situ and Southern blot hybridization techniques as well as the development and application of newer techniques including the polymerase chain reaction.

In conclusion, with the use of in situ hybridization to show HPV type 16 DNA in tumor metastases within lymph nodes we have provided additional evidence that implicates HPV infection with lower genital carcinogenesis. In situ hybridization offers the advantages of repeated assay along with its use of formalin-fixed, paraffin-embedded tissues, but seems to suffer from assay sensitivity. Both in situ hybridization and Southern blotting may provide important information on the HPV-related molecular biology of invasive and preinvasive lesions in the lower genital tract.

Vasodilatory effects of nifedipine, methoxyverapamil, and sodium nitroprusside on contractile responses of the ewe uterine artery at term pregnancy

Miguel Isla, DVM, PhD, and Donald C. Dyer, PhD
Ames, Iowa

The differential inhibitory effect of the vasodilators on contractile responses to norepinephrine, serotonin, and potassium on isolated uterine artery ring segments from pregnant ewes within 2 weeks of term was quantified and correlated with the source of Ca^{++} for the vasoconstrictors producing the smooth muscle contraction. The contraction evoked by the vasoconstrictors was dependent on extracellular Ca^{++} and in agonist-induced contractions also on an intracellular pool of Ca^{++}. Nifedipine effectively inhibited K^+-induced (90 mmol/L) contractions (antagonist concentration to reduce the maximum contractile effect to the agonist to 50%, $1.95 \pm 0.9 \times 10^{-8}$ mol/L), whereas it was relatively ineffective in blocking norepinephrine-induced (10^{-5} mol/L) or serotonin-induced (10^{-5} mol/L) vasoconstriction (antagonist concentration to reduce the maximum contractile effect to the agonist to 50%, $1.38 \pm 0.4 \times 10^{-4}$ mol/L and $2.04 \pm 0.4 \times 10^{-5}$ mol/L, respectively). Methoxyverapamil (D-600) strongly inhibited serotonin-induced contractions (antagonist concentration to reduce the maximum contractile effect to the agonist to 50%, $3.3 \pm 0.3 \times 10^{-7}$ mol/L). The phasic rather than the tonic components of the serotonin- and norepinephrine-induced contractions were more effectively inhibited by D-600 ($p < 0.05$). Sodium nitroprusside preferentially blocked ($p < 0.05$) the sustained tonic components of norepinephrine- and serotonin-induced vasoconstrictions (antagonist concentration to reduce the maximum contractile effect to the agonist to 50%, $7.1 \pm 0.4 \times 10^{-7}$ mol/L and $8.2 \pm 0.6 \times 10^{-7}$ mol/L, respectively). On the basis of these findings it is concluded that D-600 and sodium nitroprusside are more effective than nifedipine in blocking contractile responses due to receptor stimulation, and therefore might be more effective in the treatment of hypertensive emergencies in which these amines might be implicated. (Am J Obstet Gynecol 1990;163:1337-44.)

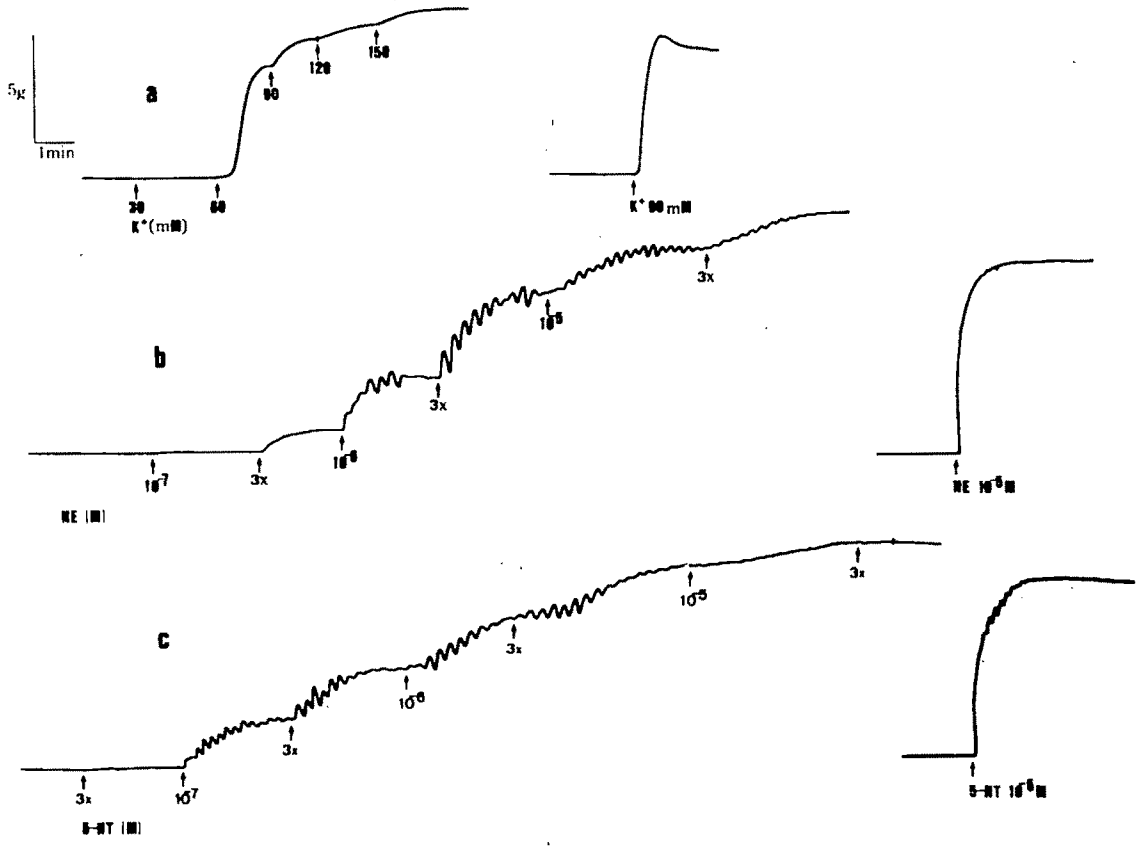
Nifedipine, methoxyverapamil (D-600, A. G. Knoll Pharmaceutical Laboratories, Ludwigshafen, West Germany), and sodium nitroprusside have been used in human beings to counteract pregnancy-induced hypertension.[1, 2, 3] The mechanisms responsible for the vasodilation effects of these agents are not clearly established. Nifedipine is a dihydropiridine Ca^{++} antagonist that has marked selectivity for potential dependent Ca^{++} channels in vascular smooth muscle.[4] D-600 has approximately equiactive effects in blocking poten-

tial dependent Ca^{++} channels in cardiac muscle and vascular smooth muscle,[5] and has been recently shown to interact with certain neurotransmitter receptors, specifically serotonin receptors.[6-8] On the other hand, nitrovasodilators such as sodium nitroprusside interfere with contractile responses due to receptor stimulation, which putatively increases myoplasmic free Ca^{++} either by releasing intracellularly stored Ca^{++} or by acting directly on Ca^{++} channels linked to the receptor.[9]

The pregnant ewe is widely used as an experimental animal in the study of maternal-fetal physiology-pharmacology. We recently showed in the late pregnant ewe isolated uterine artery that norepinephrine and serotonin induce long-lasting, strong vasoconstrictor responses through the stimulation of α_1-adrenergic and $5HT_2$ (serotonergic) receptors, respectively.[10, 11] A pronounced vasoconstriction in the uterine circulation induced by these agonists could have a detrimental effect on the proper functioning of reproductive organs and perfusion of the fetus as in pregnancy-induced hypertension.

In this study we compare the effects of nifedipine, D-600, and sodium nitroprusside on contractions induced by norepinephrine, serotonin, and K^+ depolarization with the aim of providing additional information for the clarification of the vasoinhibitory action of these agents. Particular attention is given to the determination of the Ca^{++} source for the agonist producing the smooth muscle contraction, inasmuch as the final determinant of vasoconstriction appears to be an increase in intracellular free Ca^{++}.

Material and methods



Specimens of uterine arteries were obtained from pregnant ewes within 2 weeks of term (131 to 145 days' gestation). Animals were killed by intravenous injection of pentobarbital and exsanguination. Immediately after exsanguination, sections of the mesometrium and uterus that contain the uterine arteries were placed in ice-cold oxygenated modified Krebs-Henseleit solution and taken to the laboratory. The Krebs-Henseleit solution had the following composition (mmol/L): sodium chloride 115.21, sodium bicarbonate 22.14, potassium chloride 4.7, magnesium sulfate 1.16, potassium dihydrogen phosphate 1.2, ethylenediaminetetraacetic acid ($2H_2O$) 0.003, dextrose 7.88, and calcium chloride 1.8. The uterine arteries were dissected from the adhering tissues and isolated arterial rings were prepared as described previously.[12] In brief, rings with an outer diameter of 3 to 4 mm and a width of about 3 mm were obtained from the main uterine artery before the first bifurcation. Preparations were mounted between two stainless-steel hooks in 10 ml organ baths containing Krebs-Henseleit solution at 37° C and oxygenated with a mixture of 5% carbon dioxide and 95% oxygen. Changes in isometric force were monitored by transducers (Grass FTO3C, Grass Instrument Co., Quincy, Mass.) and recorded on a polygraph (Grass model 79D) or a Beckman recorder.

The preparations were allowed to equilibrate during a period of 90 minutes. During this time the tissues were washed every 10 to 15 minutes and basal tension was repeatedly adjusted until the resting tension became stable at 1 *g*. A contraction to K^+ 90 mmol/L was obtained after the 90 minutes of equilibration and served as a control for the reproducibility of the contractions and as an internal standard for each vessel segment.[13]

Cumulative dose-response curves to norepinephrine (10^{-8} to 3×10^{-5} mol/L), serotonin (10^{-8} to 3×10^{-5} mol/L), and K^+ (9 to 150 mmol/L) were obtained. Single concentrations of the vasoconstrictors (norepinephrine, 10^{-5} mol/L, serotonin, 10^{-5} mol/L, K^+ 90 mmol/L) were used in studies with vasoinhibitors because the responses to these vasoconstrictors were reproducible during the course of the experiment.

The effect of calcium removal on the contractions induced by norepinephrine (10^{-5} mol/L), serotonin (10^{-5} mol/L), and K^+ (90 mmol/L) was ascertained by omitting calcium chloride from the Krebs-Henseleit solution. Tissues were incubated for 30 minutes in the Ca^{++}-free Krebs solution containing 0.1 mmol/L ethyleneglycol-bis-(β-aminoethylether)-N,N,N',N'-tetraacetic acid (EGTA) (rinsed every 10 minutes) before the application of a vasoconstrictor. This procedure was repeated until the residual response to the vasoconstrictor was completely abolished. Then in the presence of a vasoconstrictor, Ca^{++} was added to the bath in a dose-dependent fashion (0.25 to 2.5 mmol/L) to restore contractile activity of the tissue.

Two different procedures were used to examine the effects of nifedipine, D-600, and sodium nitroprusside on the contractile responses to norepinephrine, serotonin, and K^+. In one group of experiments, after contractile control-responses to the vasoconstrictors were obtained, the tissues were treated with the vasoinhibitors for 30 minutes and then stimulated with the same agent. The tissues were washed extensively for 45 minutes and the next higher concentration of the same vasoinhibitor was added. This procedure was repeated until the vasoinhibitor dose-response curves were completed. In the other procedure, when the contractile responses to norepinephrine or serotonin had stabilized, a vasoinhibitor was added to the bath in increasing concentrations to ascertain its effect on the precontracted arteries. To reduce sites of loss (neuronal uptake and metabolism by catechol-O-methyltransferase) of the amine agonists from the receptor sites in the arteries, cocaine (10^{-5} mol/L) and tropolone (10^{-5} mol/L) were added to the bath 20 min-

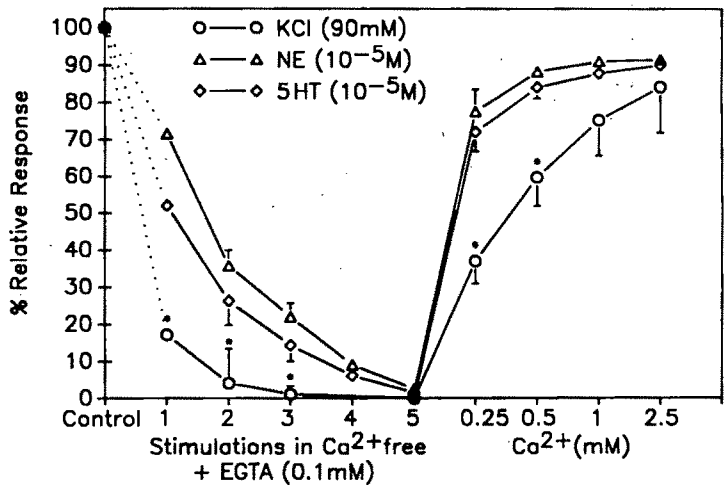

Fig. 2. Effect of replacement of Krebs-Henseleit solution (1.8 mmol/L Ca^{++}) with calcium-free solution containing EGTA (0.1 mmol/L) on the contractions induced by norepinephrine *(NE)* 10^{-5} mol/L, serotonin *(5-HT)* 10^{-5} mol/L, and K^+ 90 mmol/L. Tissues were stimulated every 30 minutes in calcium-free solution until responses were completely abolished. In presence of stimulating agents, calcium was then added to bath in dose-dependent fashion (0.25 to 2.5 mmol/L). Each point is mean ± SE of seven experiments. *Asterisks* indicate significant difference between corresponding points ($p < 0.05$).

norepinephrine required to produce 50% of the maximal response (ED_{50}) was 1.8 ± 0.3 × 10^{-6} mol/L. The addition of a single, submaximal concentration of norepinephrine (10^{-5} mol/L) to the tissue bath induced a fast and stable contraction of the uterine artery (160.0% ± 6.2% of K^+ 90 mmol/L; $n = 10$). The contraction to norepinephrine (10^{-5} mol/L) remained stable for more than 15 minutes (Fig. 1, *b*).

Serotonin (10^{-7} – 10^{-4} mol/L) induced concentration-dependent contractions. The concentration of serotonin required to produce 50% of its maximal response (11.3 ± 0.7 mN; $n = 10$) was 4.4 ± 0.4 × 10^{-7} mol/L and the maximal response to that of the K^+ maximum was 156.3% ± 9.1%, $n = 10$. A submaximal concentration of serotonin (10^{-5} mol/L) induced a contraction that was fast in onset and maintained a stable level of tension (143.3% ± 5.1% of K^+ 90 mmol/L, $n = 10$) for >15 minutes (Fig. 1, *c*).

Calcium sources. Calcium removal from the Krebs-Henseleit solution and the addition of EGTA (0.1 mmol/L) progressively reduced the response to the vasoconstrictors. After the second stimulation with K^+ (90 mmol/L) or the fourth stimulation with norepinephrine (10^{-5} mol/L) or serotonin (10^{-5} mol/L), the contractile response to each of the respective vasoconstrictors was completely abolished (Fig. 2). The subsequent administration of Ca^{++} back to the Krebs-Henseleit solution caused the tissue to regain activity to the vasoconstrictors, even to small concentrations of Ca^{++} (0.25 mmol/L). This recovery was more marked ($p < 0.05$) when norepinephrine or serotonin were the agonists than when the tissues were depolarized with potassium (Fig. 2).

Effect of pretreatment with nifedipine, D-600, and sodium nitroprusside. The effect of pretreatment of the tissues with the vasodilators against the contractile responses of norepinephrine (10^{-5} mol/L), serotonin (10^{-5} mol/L), and K^+ (90 mmol/L) is represented in Figs. 3, *A*, 4, *A*, and 5, respectively. The collected ID_{50} values and relative potencies are presented in Table I.

Nifedipine was more active ($p < 0.05$) in inhibiting K^+ than norepinephrine, and serotonin induced vasoconstriction. D-600 more effectively inhibited ($p < 0.05$) K^+- and serotonin-induced contractions than norepinephrine-induced vasoconstrictions, whereas sodium nitroprusside was equieffective against the three agonists.

Effect of nifedipine, D-600, and sodium nitroprusside on precontracted arteries. The vasodilators in a concentration-dependent manner relaxed arteries precontracted with either norepinephrine (10^{-5} mol/L) or serotonin (10^{-5} mol/L). The potency order for inhibiting either norepinephrine or serotonin precontracted rings was the same: sodium nitroprusside, D-600, nifedipine (Figs. 3, *B*, and 4, *B*). The ID_{50} values, the relative potency of the vasodilators, and the maximum inhibitory effect are presented in Table II.

A comparison of the inhibitory effects of the vasodilators on pretreated versus precontracted arteries indicated that D-600 was more active ($p < 0.05$) in inhibiting norepinephrine and serotonin vasoconstrictions when preincubated with the tissues than when

administered to the precontracted arteries, whereas sodium nitroprusside when administered to the norepinephrine- and serotonin-precontracted arteries was significantly more effective ($p < 0.05$) (Figs. 3 and 4).

Comment

The results in the present study illustrate the differential inhibitory effect of nifedipine, D-600, and sodium nitroprusside on contractile responses to norepinephrine, serotonin, and potassium. Potassium-induced (90 mmol/L) contractions were completely abolished after the second stimulation in the Ca^{++}-free medium. The contraction gradually recovered when Ca^{++} was readded to the solution, indicating a complete dependency on extracellular Ca^{++} of the contraction to K^+. Nifedipine was very active in antagonizing the K^+-depolarized response of uterine blood vessels. Because nifedipine has a marked selectivity for potential dependent Ca^+ channels in vascular smooth muscle,[4] it could be suggested that in the uterine artery Ca^{++} influx through these channels is essential for the contraction of K^+ depolarization. The lack of effect of

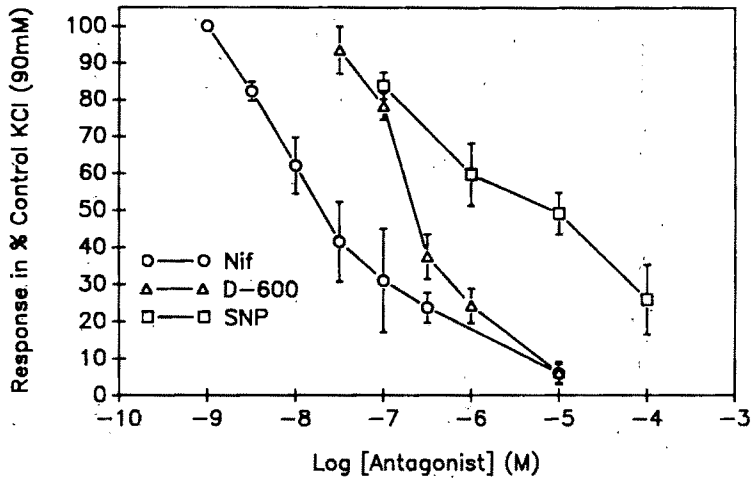

Fig. 5. Inhibitory effect of nifedipine *(Nif)*, methoxyverapamil *(D-600)*, and sodium nitroprusside *(SNP)* on isolated ring segments of late pregnant ovine uterine arteries contracted by 90 mmol/L potassium chloride. Tissues were equilibrated with the vasodilators for 30 minutes before addition of potassium chloride. *Vertical bars* represent SE of five experiments.

phentolamine (10^{-7} mol/L) on the K^+-induced contraction suggests that K^+ does not release norepinephrine from adrenergic nerve terminals in the ovine uterine artery at term as was found by Fallgren and Edvinsson[13] in the guinea pig uterine artery, and might, in part, explain the decay of the tonic contraction to K^+ (90 mmol/L) depolarization.

On the other hand, norepinephrine- and serotonin-induced contractions were much more resistant to Ca^{++} removal. The addition of minimal quantities of Ca^{++} (0.25 mmol/L) produced an almost complete recovery of the maximal contractile effect to norepinephrine and serotonin. This suggests a high calcium sensitivity of the contractile system in the arterial smooth muscle of the ovine uterine artery from pregnancy. As has been shown in the human[16] and guinea pig uterine artery[17] vasoconstriction relies mainly on the presence of extracellular calcium and in the case of drug-induced contractile responses also on an intracellular pool of calcium.

Nifedipine was the least active of the three vasodilators in inhibiting the contractions induced by norepinephrine or serotonin. Neither pretreatment of the tissues with the highest concentrations of nifedipine (10^{-4} mol/L) nor administration of nifedipine (10^{-8} to 10^{-4} mol/L) to the precontracted arteries completely abolished norepinephrine- and serotonin-induced vasoconstriction. These results are consistent with the findings that norepinephrine and serotonin activate respectively α_1-adrenergic and $5HT_2$ (serotonergic) receptors[10, 11] and presumably Ca^{++} influx occurs through receptor operated nifedipine insensitive Ca^{++} channels. It might be suggested that the use of nifedipine for the treatment of pregnancy-induced hypertension requires further study because even though it might decrease maternal blood pressure it does not block the vasoconstrictor response to norepinephrine and serotonin and therefore would not be expected to cause vasodilatation in the uterine vasculature if these amines were involved in the hypertension. This observation is in agreement with the results obtained by Veille and coworkers[18] with pregnant animal models in which nifedipine did not alter the uterine flow appreciably and did not cause excessive hypotension. However, as a second-line antihypertensive drug in pregnancy in a slow release preparation, nifedipine has been found to be an effective antihypertensive in human patients.[3]

In this study when D-600 was incubated with the uterine arteries, the contractile responses to serotonin and K^+ were more effectively inhibited than those to norepinephrine. D-600, when preequilibrated with the tissue, was 30 times more active than nifedipine and sodium nitroprusside in inhibiting the serotonin-induced vasoconstriction, whereas it was 10 times less active than nifedipine in inhibiting the contraction to K^+ depolarization. These results taken together suggest that D-600 is very active in blocking serotonin-induced vasoconstrictions. These results are in agreement with those of Auguet and colleagues[7, 8] in studies on isolated rabbit aorta in which they found that D-600 and verapamil in addition to blocking potential dependent calcium channels can also interact with certain neurotransmitter receptors and are very potent competitive antagonists of serotonin-induced vasoconstrictions. In the uterine artery, D-600 seems to be somewhat more selective in blocking serotonin receptors and therefore it might be best characterized as a Ca^{++}-serotonin an-

Table I. Inhibitory effect of nifedipine, sodium nitroprusside, and D-600 on the contractile responses to norepinephrine (10^{-5} mol/L), serotonin (10^{-5} mol/L), and high extracellular potassium (90 mol/L) in the late pregnant ovine uterine artery

	Norepinephrine (10^{-5} mol/L)		*Serotonin (10^{-5} mol/L)*		*K^+ (90 mmol/L)*	
	ID_{50} (mol/L)	*Relative potency*	*ID_{50} (mol/L)*	*Relative potency*	*ID_{50} (mol/L)*	*Relative potency*
Nifedipine	$1.38 \pm 0.4 \times 10^{-4}$	0.11	$2.04 \pm 0.4 \times 10^{-5}$	0.036	$1.95 \pm 0.9 \times 10^{-8}$*	11.64
Sodium nitroprusside	$2.05 \pm 0.5 \times 10^{-5}$	0.59	$7.80 \pm 0.5 \times 10^{-6}$	0.031	$8.40 \pm 0.7 \times 10^{-6}$	0.09
D-600	$4.98 \pm 0.6 \times 10^{-6}$*	1.00	$3.30 \pm 0.3 \times 10^{-7}$	1.000	$2.15 \pm 0.4 \times 10^{-7}$	1.00

The vasodilators were allowed to equilibrate with the tissues 30 minutes before a subsequent stimulation was obtained. The concentration of vasodilator reducing the maximum contractile effect to 50% (ID_{50}) was determined graphically by linear interpolation. Relative potency of the vasodilators was determined by the method of the 2-and-2 dose assay[15] by assigning D-600 a potency of 1. Values are mean ± SE of five to seven different animals.

*Significant differences of a vasodilator between vasoconstrictors ($p < 0.05$).

Table II. Inhibitory effect of nifedipine, sodium nitroprusside, and D-600 on the contractile responses to norepinephrine and (10^{-5} mol/L) and serotonin (10^{-5} mol/L) in the late pregnant ovine uterine artery

	Norepinephrine			*Serotonin*		
	ID_{50} (mol/L)	*Imax (%)*	*Relative potency*	*ID_{50} (mol/L)*	*Imax (%)*	*Relative potency*
Nifedipine	$9.6 \pm 0.3 \times 10^{-6}$	54.8 ± 3.9	0.98	$5.8 \pm 0.4 \times 10^{-6}$*	37.0 ± 4.1	0.44
Sodium nitroprusside	$7.1 \pm 0.4 \times 10^{-7}$	93.1 ± 2.5	11.02	$8.2 \pm 0.6 \times 10^{-7}$	83.8 ± 5.4	1.47
D-600	$6.9 \pm 0.5 \times 10^{-6}$	63.6 ± 4.0	1.00	$4.7 \pm 0.9 \times 10^{-6}$*	91.3 ± 2.9	1.00

The vasodilators were administered at increasing concentrations to the precontracted arteries. The concentration of vasodilator relaxing the precontracted artery to the 50% (ID_{50}) level was determined graphically by linear interpolation. *Imax* refers to the greatest inhibition observed to that vasodilator. Relative potency of the vasodilators was determined by the method of the 2-and-2 dose assay,[15] by assigning D-600 a potency of 1.

*Significant difference between the same treatment for the two vasoconstrictors ($p < 0.05$).

tagonist rather than as a pure Ca^{++} entry blocker. Accordingly, the significantly higher inhibitory effect of D-600 on the phasic rather than on the sustained component of the serotonin-induced contraction could be explained by its competitive antagonism on the serotonin receptor. The combined Ca^{++}-serotonin antagonism might be of interest in the treatment of pregnancy-induced hypertension. In this sense Serafini and collaborators[1] reported that D-600 administered intravenously to patients decreased the maternal blood pressure without compromising the fetus.

On the other hand, the sustained rather than the phasic component of the serotonin- or norepinephrine-induced contraction was more effectively blocked ($p < 0.05$) by sodium nitroprusside. This differential inhibitory effect of sodium nitroprusside might indicate that several Ca^{++} pathways can be activated by these agonists during the course of the contraction. In this sense it has been suggested in vascular smooth muscle that contractile responses to vasoactive agonists such as norepinephrine and serotonin are initiated by intracellular Ca^{++} release and maintained by an influx of extracellular Ca^{++}.[19, 20] Hence, in the uterine artery, sodium nitroprusside, seems to be blocking the influx of extracellular Ca^{++} rather than affecting the intracellular Ca^{++} pools. It is of particular interest to note that sodium nitroprusside can effectively inhibit the sustained contractions to norepinephrine and serotonin in the isolated ovine uterine artery, whereas a sustained contraction of the uterine vasculature in vivo might compromise the fetus.

Contradictory results have been obtained when sodium nitroprusside was administered to reverse hypertension in chronically instrumented pregnant ewes. Some animals required high rates of infusion of sodium nitroprusside (25 μg/kg/min)[21, 22]; whereas for others, low rates of infusion (<1 to 3 μg/kg/min) were enough to maintain the desired 20% decrease in mean maternal pressure.[22, 23] In the former no change or decreased uterine blood flow was reported and fetal death occurred within 30 minutes of cessation of sodium nitroprusside infusion because of cyanide toxicity. However, in the latter the safety of this therapy for both mother and fetus was shown. Whereas caution must be taken in the extrapolation of data from in vitro studies, our results with sodium nitroprusside in isolated late pregnant ovine uterine artery confirm the results obtained by Nelson and Suresh[24] in pregnant and non-

pregnant human uterine arteries and provide a rationale for the use of sodium nitroprusside in hypertensive emergencies in pregnant patients if standard therapy has failed.

In conclusion, the results of this study show that nifedipine, D-600, and sodium nitroprusside induce dilatation of uterine arteries from near-term pregnany ewes: (1) nifedipine effectively inhibits K^+-induced contractions but is relatively ineffective in blocking norepinephrine- and serotonin-induced contractions; (2) D-600 is more effective on the phasic than on the tonic component of the contractions to norepinephrine and serotonin and is specifically active in inhibiting serotonin-induced contractions, being best characterized in this tissue as a Ca^{++}-serotonin antagonist rather than as a pure Ca^{++} entry blocker; and (3) sodium nitroprusside preferentially inhibits the sustained tonic component of norepinephrine- and serotonin-induced vasoconstrictions.

Fetal and maternal response to intravenous infusion of a thromboxane synthetase inhibitor

John P. Cardin, Jr., MD,[a] Michael G. Ross, MPH, MD,[a] M. Gore Ervin, PhD,[a] A. Victoria Schaffer, MD,[b] Frank L. Douglas, PhD, MD,[b] and John P. Simke[b]

Torrance, California, and Summit, New Jersey

Pharmacologic inhibition of thromboxane synthetase activity has reversed the clinical manifestations of toxemia in the ovine model. To investigate placental transfer and fetal effects of a selective thromboxane synthetase inhibitor, CGS13080 (Ciba-Geigy, Summit, N.J.) was intravenously infused into eight singleton- or twin-bearing ewes near term. During CGS 13080 infustion (0.1 mg/kg/hr), maternal steady-state CGS 13080 levels of 102 ± 18 ng/ml were achieved within 30 minutes and maternal serum thromboxane generation decreased significantly (13 ± 3 to 4 ± 1 ng/ml). However, fetal serum levels of CGS 13080 were only 4% of peak maternal concentrations and fetal serum thromboxane generation did not change. There was no evidence of change in uterine blood flow, maternal or fetal blood pressure, heart rate, blood gas values, or fetal or maternal metabolites of prostacyclin or prostaglandin E_2 during the study. We speculate that CGS 13080 may be efficacious in the treatment of human pregnancy-induced hypertension. (AM J OBSTET GYNECOL 1990;163:1345-9.)

Key words: Pregnancy-induced hypertension, thromboxane synthetase inhibitor, pregnancy, CGS 13080, sheep

Pregnancy-induced hypertension is a leading cause of maternal and perinatal morbidity and mortality and occurs in approximately 6% of all pregnancies.[1] Although the precise cause of pregnancy-induced hypertension is unknown, alterations in prostaglandin metabolite production are believed to be central to the pathophysiology. Several investigators have suggested that a prostacyclin deficiency occurs in both maternal and fetal circulations.[2-7] This may result in an imbalance in the prostacyclin-to-thromboxane ratio and account for the many clinical manifestations of pregnancy-induced hypertension. Recent evidence indicates that selective thromboxane synthetase inhibitors may be efficacious in the treatment of pregnancy-induced hypertension. In several case reports women with pregnancy-induced hypertension showed clinical improvement in response to infusion of a thromboxane synthetase inhibitor.[8, 9] In an ovine toxemia model (starvation-induced) Keith et al.[10] demonstrated complete reversal of the pathophysiologic changes and a significant increase in plasma prostacyclin levels after intravenous thromboxane synthetase inhibitor administration. Although a thromboxane synthetase inhibitor may have clinical efficacy, there is limited knowledge of the effects of maternal infusion on the fetus.

The purpose of this study was to quantitate the placental transfer of the thromboxane synthetase inhibitor CGS 13080 (Ciba-Geigy, Summit, N.J.) when infused to the maternal ewe and to determine the effects of CGS 13080 on both ovine maternal and fetal prostaglandin levels during maternal drug infusions.

Material and methods

Eight Western mixed-breed ewes with both singlet (n = 5) and twin (n = 3) fetuses were studied at a mean (± SEM) gestation of 132 ± 2 days. Guidelines for the care and use of animals approved by Harbor–University of California at Los Angeles Medical Center were followed. The animals were housed indoors in individual steel cages and were acclimated to surroundings for at least 4 days before operation. All animals were operated on between 124 and 130 days' gestation and allowed 4 to 5 days of recovery before study.

At operation, anesthesia was induced by an intramuscular injection of ketamine hydrochloride (750 mg) followed by continuous intravenous infusion of ketamine (600 mg/hr) and locally applied lidocaine (1%). After sterile preparation and draping, a midline incision exposed both uterine horns. After the position of

the fetus was determined, a single hind leg was exposed through a small hysterotomy. Polyethylene catheters (inside diameter, 1.0 mm; outside diameter, 1.8 mm) were inserted in the dorsal hind limb vein and artery and threaded to the inferior vena cava and abdominal aorta, respectively. Before hysterotomy closure, a plastic catheter (Corometrics Medical System, Inc., Wallingford, Conn.) was sutured to the fetal hind limb. If twins were present, the above procedure was repeated for the second fetus. In four animals the left uterine artery was isolated and an electromagnetic flow probe (Dienco, Los Angeles) was sutured in place. All catheters were exteriorized to the maternal flank and placed in a cloth pouch sewn to the ewe's flank. The maternal artery and vein were catheterized at the femoral triangle and threaded to the descending aorta and inferior vena cava, respectively. To maintain catheter patency, the fetal vascular catheters were filled with 1000 U/ml of sodium heparin and maternal catheters with 10 U/ml of sodium heparin. Catheters were sealed with sterile caps and flushed daily. Ewes were administered intravenous gentamicin 80 mg, chloromycetin 600 mg, and oxacillin 500 mg before operation and twice daily for 3 days after operation.

Experimental protocol. Experiments were performed on unanesthetized animals after a minimum of 5 days of recovery. Animals were studied in the same individual cages in which they were maintained. All animals were weighed before drug infusion. The thromboxane synthetase inhibitor imidazo-(1,5-2)-pyridine-5-hexanoic acid (CGS 13080) obtained in a powdered form was dissolved in water to achieve a final concentration of 0.67 mg/ml. To effectively dissolve CGS 13080 into solution, the pH was adjusted to 7.4 with 50 mmol/L Tris base and the temperature raised to 40° to 45° C.

The study design included a 30-minute control period (−30 to 0 minutes), a 3-hour infusion (0 to 180 minutes) of CGS 13080 (0.1 mg/kg/hr) into the maternal venous catheter and a recovery phase (180 to 360 minutes). Fetal and maternal arterial blood samples (2.5 ml) were obtained at −30, 0, 30, 60, 120, 180, 240, 300, and 360 minutes. In two of the three pairs of twins both fetuses were sampled and monitored. An arterial blood sample (1 ml) was collected at each time interval and allowed to clot at 37° C for 1 hour before centrifugation. Serum was stored at −20° C until assayed for the serum prostaglandin metabolites prostaglandin E_2 (PGE_2), 6-keto-prostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$), and thromboxane B_2 (TXB_2). In addition, 1 ml of blood was collected in 10 μl of 0.1mol/L lithium heparin, and an aliquot was taken to measure the hematocrit before centrifugation. The plasma was stored at −20° C until assayed for CGS 13080. Finally, 0.5 ml of blood was collected in a heparinized tuberculin syringe for immediate measurement of pH, Po_2, and Pco_2. Blood gases and pH were determined at 39° C with a Bm 33 MK2-PHM 72 MKS acid-base analyzer system (Radiometer Co., Copenhagen). After each sample, the fetal blood was replaced with an identical volume of maternal heparinized blood withdrawn before the study. Maternal samples were replaced with saline solution. Fetal and maternal arterial blood pressure, heart rate, and amniotic pressures were continuously monitored with an R-612 physiologic recorder (Beckman, Palo Alto). Fetal pressures were corrected for amniotic fluid pressures.

Determination of plasma CGS 13080 concentration. CGS 13080 concentrations were determined by high-performance liquid chromatography analysis.[11] Briefly, plasma samples (100 μl) were added with standard CGS 13080 (100 ng in 25 μl) and diluted with distilled water (1 ml). The mixture was loaded onto a 1 ml Bond Elut SCX minicolumn (Analytichem, Harbor City, Calif.) previously washed with distilled water (3 ml). CGS 13080 was then eluted with 2 ml of 4% ammonium hydroxide in methanol. The eluent was evaporated to dryness under nitrogen and reconstituted in 250 μl before high-performance liquid chromatography analysis. An aliquot (50 μl) of the extract was injected onto a Beckman Ultrasphere C18 analytical column. The flow rate was 1.5 ml/min and the eluent was monitored for fluorescence with a model 980 detector (The Anspec Co., Ann Arbor) equipped with a 418 nm filter. Calibration was performed with authentic CGS 13080 in blank human plasma samples. The limit of detection of CGS 13080 was 5 ng/ml. Standard curves were linear over the entire range of detection from 5 ng/ml to 3 μg/ml. The interassay variation was 3%. Chromatograms for controls (blank) plasma samples did not contain any peaks at the retention time for CGS 13080. Because of the limit of sensitivity, measurable background interference was noted in blank plasma samples. Background values obtained during the control period were subtracted from each value obtained during the infusion and recovery periods.

Eicosanoid assays. Measurements of serum TBX_2, 6-keto-$PGF_{1\alpha}$, and PGE_2 were performed by radioimmunoassay. Prostanoid metabolite standards were obtained from The Upjohn Company, Kalamazoo, and stock solutions of 1 mg/ml in 10% (v/v) acetonitrile in water were prepared, diluted to 100 ng/ml, and stored at 4° C. Dilutions of standard compounds ranging from 0.072 to 18 ng/ml or of unknown samples were made in 0.05 mol/L Tris hydrochloride (pH 6.8) containing 0.9% (sodium chloride, 0.3% bovine serum albumin, 0.05% sodium azide, and 0.01 mol/L ethylenediamine tetraacetic acid to construct a standard curve. The 50% binding level of the standard curve was 1.5 ng/ml. Iodine 125 methyl esters of TXB_2, 6-keto-$PGF_{1\alpha}$ and

PGE_2, all at 2200 Ci/mmol, were obtained from Advanced Magnetics, Inc., Cambridge, Mass. as were rabbit antisera to TXB_2, 6-keto-$PGF_{1\alpha}$, and PGE_2. Samples were assayed in duplicate. Standards or samples were mixed with ^{125}I-tracer (12,000 cpm), and the appropriate rabbit antiserum (all reagents at predetermined optimal levels) was added. The mixture was incubated for 16 hours at 4° C in 25 × 75 mm tubes, and then an excess of goat antirabbit antibody bound to paramagnetic particles was added. The magnetic complexes were separated by attraction to the tube wall by means of a magnetic rack. The bound radioactivity was determined with a Laboratory Technologies 25-well γ-counter. Sample dilutions were adjusted to give results falling between 20% and 80% of maximum binding; under these conditions the lowest quantifiable value was 0.3 ng/ml. Intraassay variation between replicates was 5% and total interassay variance was 12%.

Calculations and statistics. The steady-state maternal plasma CGS 13080 clearance rate was calculated as: Infusion rate of CGS 13080/(CGS 13080 concentration at steady state). Mean residence time was calculated as: Plasma volume/Plasma clearance rate, where the plasma volume was calculated on the basis of an assumed blood volume of 56 ml/kg for the adult ewe.[12]

All values are reported as mean ± SEM. Differences over time were assessed by one-way analysis of variance. If a significant F test was present, Dunnett's test was applied to compare control means to each group mean.

Results

In response to intravenous infusion of CGS 13080, the maternal plasma CGS 13080 levels increased to 102 ± 18 ng/nl. A steady-state concentration was achieved by 30 minutes of infusion. After discontinuation of the infusion, maternal plasma CGS 13080 decreased linearly to a nadir of 10 ± 6 ng/ml at 3 hours of recovery (Fig. 1). Fetal plasma CGS 13080 became detectable during maternal infusion (4.2 ± 0.5 ng/ml, $p < 0.05$) at levels approximately 4% of peak maternal values. However, fetal plasma CGS 13080 was nondetectable by the end of the 3-hour recovery period.

As expected, maternal serum TXB_2 decreased significantly (13.2 ± 2.9 to 3.6 ± 0.9 ng/ml, $p < 0.05$) during CGS 13080 infusion and the levels returned to near normal at the completion of the recovery phase. However, fetal serum TXB_2 did not change significantly ($p > 0.05$) during the study (Fig. 1). Maternal and fetal 6-keto-$PGF_{1\alpha}$ and PGE_2 levels did not change during the study (Fig. 1).

The steady-state plasma clearance was 16.3 ml/min/kg and the mean residence time was 2.80 minutes.

Maternal or fetal heart rate, mean arterial pressure, arterial blood gas, hematocrit, uterine blood flow, and amniotic fluid pressures did not change (Table I).

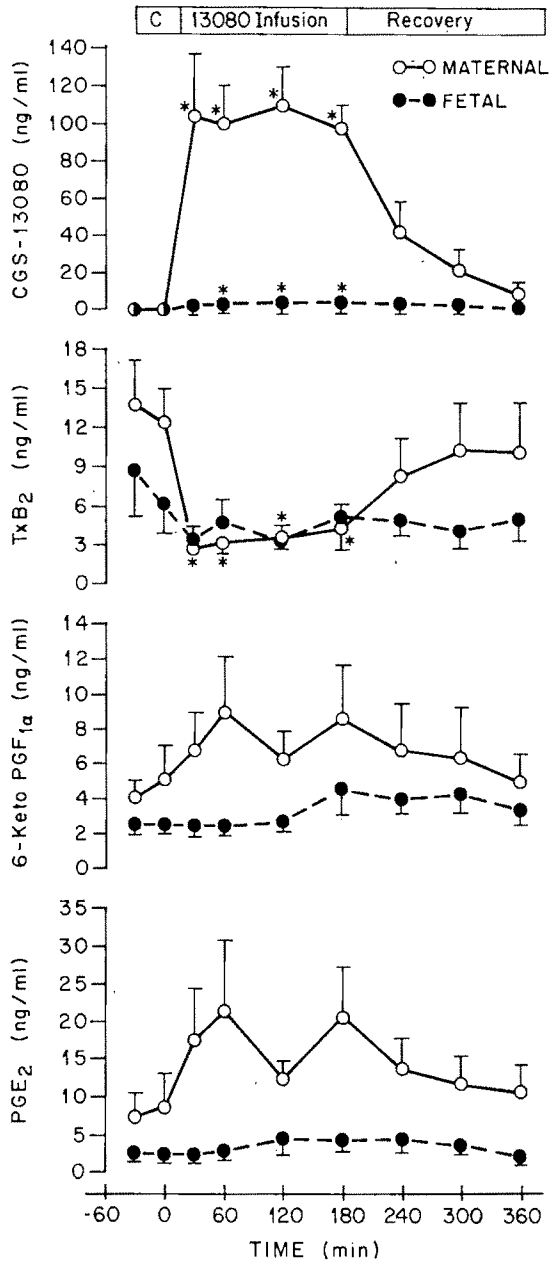

Fig. 1. Maternal and fetal plasma CGS 13080, TXB_2, 6-keto-$PGF_{1\alpha}$, and PGE_2 concentrations before, during, and after infusion of CGS 13080 to pregnant ewes. *Asterisk*, $p < 0.05$ versus mean basal value.

Comment

During normal pregnancy the production of prostacyclin increases by fivefold.[13] Available evidence supports the view that this increase contributes to the overall physiologic vasodilatation and decreased vascular resistance characteristics of early gestation. However, for unknown reasons a prostacyclin-deficiency state

Table I. Maternal and fetal arterial values (mean ± SEM) before, during, and after infusion of CGS 13080 to the maternal ewe

	Control	*Infusion*	*Recovery*
Maternal (n = 8)			
Hematocrit (%)	28.0 ± 0.5	28.0 ± 0.7	27.8 ± 0.4
pH	7.47 ± 0.01	7.47 ± 0.02	7.49 ± 0.01
Heart rate (beats/min)	118 ± 5	113 ± 3	114 ± 5
Mean arterial pressure (mm Hg)	78 ± 3	79 ± 2	83 ± 3
Uterine blood flow (ml/min)	304 ± 14	297 ± 10	312 ± 10

Amniotic fluid pressure (mm Hg)	5.9 ± 1.2	6.2 ± 1.2	7.0 ± 1.3

may develop in pregnancies predestined to have preeclampsia.[2-7] There is increasing evidence that patients with mild to severe pregnancy-induced hypertension show enhanced platelet activation and consumption[14] while placentas of patients with pregnancy-induced hypertension exhibit increased generation of thromboxane in vitro.[6] This results in an imbalance of thromboxane (vasoconstrictor) and prostacyclin (vasodilator). If the role of this imbalance is central to the pathophysiologic features of preeclampsia, then the use of selective inhibitors of thromboxane synthetase may be beneficial. Clinical studies with selective thromboxane synthetase inhibitors in pregnancy-induced hypertension are limited. An orally active thromboxane synthetase inhibitor (UK-37,248 or Dazoxiben, Pfizer Central Research, London) administered to 13 severely toxemic patients remote from term[8, 9] was shown to yield apparent clinical improvement. Six cases resulted in perinatal death attributed to prematurity and severe growth retardation, and seven resulted in live births.

The majority of research relative to the use of selective thromboxane synthetase inhibitors in pregnancy has used the ovine toxemia model as described by Thatcher and Keith.[15] Twin-bearing ewes starved for 72 hours develop many of the clinical manifestations of human toxemia. The clinical manifestations of hypertension, altered renal function and serum chemistry, and enhanced platelet aggregation can be reversed by use of selective thromboxane synthetase inhibitors (U-63,557A, The Upjohn Co., and CGS 13080).[10, 16]

CGS 13080 is a potent, selective inhibitor of thromboxane synthetase with an immediate onset of action and rapid clearance.[17] The in vitro potency of CGS 13080 as a thromboxane synthetase inhibitor is fivefold to sixfold greater than toward the other enzymes involved in arachidonic acid metabolism. Therefore the other prostaglandin endoperoxidase pathways are preserved. Although controversial, infusion of CGS 13080 to healthy humans does not result in a change from basal prostacyclin levels.[18-20] This is in accordance with our study, which demonstrated no significant change in maternal 6-keto-$PGF_{1\alpha}$ or PGE_2 during CGS 13080 infusion. However, an endoperoxide shunt may possibly occur in response to thromboxane synthetase inhibitors during pathologic conditions.[18]

Steady state was obtained within 30 minutes, with >75% inhibition of maternal serum thromboxane generation. Serum levels of thromboxane were reported because platelet aggregation ex vivo represents the most sensitive indicator of thromboxane generation.[21] As illustrated during the recovery phase, the administration of CGS 13080 resulted in a time- and dose-related inhibition of arachidonic acid–induced platelet aggregation ex vivo. The rapid clearance of CGS 13080 is consistent with data from nonpregnant human volunteers.[17] The drug is known to be metabolized to an inactive form in the liver, which is later excreted by the kidney.[17] Clinically, because of rapid plasma clearance, there is potential for titration during intravenous infusion.

This study demonstrated no effect on maternal or fetal blood pressure, heart rate, or uterine blood flow during the infusion. The absence of hypotension is in agreement with human studies that imply that thromboxane generation contributes little to the maintenance of systemic blood pressure during normotension. Unlike administration of a thromboxane synthetase inhibitor to the ovine toxemia model, which produced a rise in uterine blood flow,[10] our results suggest that uterine blood flow in the normotensive ewe may be independent of platelet thromboxane generation.

Significant CGS 13080 levels were found in fetal plasma during maternal infusions. However, these represented only 4% of peak maternal levels. CGS 13080 is known to be 96% protein-bound in plasma and poorly lipid-soluble,[17] factors that may account for the low fetal plasma levels. More important, these low fetal CGS 13080 levels were not associated with any significant changes in thromboxane generation from fetal platelets. These pharmacokinetics are limited to the ovine

model as there are significant placental structural differences in comparison with humans.[22]

We speculate that CGS 13080 may be potentially useful in treating and/or preventing pregnancy-induced hypertension. Preliminary reports suggest that prophylactic low-dose aspirin may be efficacious in the prevention of pregnancy-induced hypertension.[23, 24] Low-dose aspirin suppresses platelet thromboxane biosynthesis through inhibition of cyclooxygenase, which also could potentially affect the prostacyclin pathway.[25] The prostacyclin pathway is preserved during infusion of CGS 13080 under physiologic conditions.[18] Furthermore, the possibility exists that under pathologic conditions CGS 13080 may result in increased prostacyclin production as a result of an endoperoxide shunt. The armamentarium for the treatment of pregnancy-induced hypertension may include low-dose aspirin, thromboxane receptor inhibitors, or thromboxane synthetase inhibitors such as CGS 13080.

Special acknowledgement for their assistance in the preparation of this manuscript goes to Dr. Allan Wong and Ms. Barbara Barna-Andrusko for the plasma CGS 13080 measurements.

Long-term maternal-fetal exposure to high-low insulin concentrations alter liver but not brain insulin receptors

S. Devaskar, MD, K. McMenamy, MD, L. Holtzclaw, BS, and F. Sadiq, MD
St. Louis, Missouri

We investigated the effects of long-term (5 to 6 days) in vivo exposure to hyperinsulinemia and hypoinsulinemia on maternal and fetal rat (18 to 20 days' gestation; term ~ 21 days) brain and liver insulin receptors. Further we studied the in vitro effects of long-term insulin exposure on cultured rabbit neuronal cell insulin receptors. Long-term glucose infusions to maternal rats resulted in maternal and fetal hyperglycemia and mild hyperinsulinemia, which decreased the liver insulin receptor abundance of the mother but increased that of the fetus. Streptozotocin-induced maternal diabetes resulted in maternal and fetal hyperglycemia with hypoinsulinemia (or near-normal insulin levels) and increased maternal and fetal liver insulin receptors. The maternal and fetal brain insulin receptor abundance failed to change at high or low insulin concentrations. Similarly long-term insulin (5 μg/ml) exposure failed to alter cultured neuronal cell insulin receptors as well. We conclude that perturbations in maternal and fetal circulating insulin concentrations fail to affect the brain insulin receptors. This protective phenomenon may be critical in maintaining the normal neuronal energy balance and functioning during certain disease states such as diabetes mellitus and hyperinsulinism. (AM J OBSTET GYNECOL 1990;163:1350-6.)

Key words: Brain, insulin, receptor, fetal, down-regulation

Diabetes in pregnancy results in various metabolic changes that adversely affect both the mother and the fetus. Type I diabetes results in low insulin concentrations with concomitant hyperglycemia,[1] while type II diabetes is an insulin-resistant state associated with high insulin concentrations and hyperglycemia.[1] In both types maternal hyperglycemia is reflected in the fetus, causing hyperinsulinemia, a state that is responsible for potentiating fetal growth in the third trimester and causing macrosomia and organomegaly.[2] To support the fact that insulin is a fetal growth promoter, there are states of fetal hypoinsulinemia such as pancreatic agenesis or transient diabetes of the newborn, which cause hyperglycemia and intrauterine growth retardation.[3] Recent evidence in various animal species,[4, 5] including adult man,[6] demonstrates that circulating insulin crosses the blood-brain barrier and gains access to the brain via the cerebrospinal fluid. In vitro insulin has been demonstrated to potentiate the growth of both neurons[7] and glial cells,[8] raising the question of whether a similar biologic (hormonal) action occurs in vivo.

Insulin receptors mediate insulin action within a cell.[9] Down- or up-regulation of insulin receptors is associated with concomitant metabolic changes.[1] Long-term exposure of various adult tissues to high or low insulin concentrations results in either down- or up-regulation of the insulin receptors along with altered metabolism.[10, 11] Fetal insulin receptors, on the other hand, are resistant and have been demonstrated to up regulate in response to high insulin concentrations,[12, 13] causing a blunting effect of the hormone on fetal metabolism.[14]

Despite the demonstration of circulating insulin gaining access to the cerebrospinal fluid in various animal models,[4-6] the non-pregnant adult brain insulin receptor has expressed unique resistance to perturbations in the circulating insulin concentrations.[15, 16] Short-term administration of insulin both systemically and intracranially failed to down regulate the fetal rabbit brain insulin receptor.[17] However, in vitro, long-term rather than short-term exposure to insulin resulted in a down-regulation of chick embryo neuronal insulin receptors.[18] If a similar phenomenon occurred in the in vivo situation, long-term exposure of the maternal and fetal brain to high insulin concentrations would result in insulin receptor changes, which in turn could alter brain metabolism and growth. This is of concern, especially during the fetal stages of development, when neurogenesis is actively taking place.[19] We therefore undertook a study to investigate this possibility in the in vivo situation employing the rat as an animal model.

We produced two models: (1) a model in which both the mother and the fetus were chronically exposed to hyperinsulinemia and (2) a model in which both of them were exposed to hypoinsulinemia, and then the effects on the maternal and fetal brain and liver cross-linked insulin receptor abundance were studied.

Methods

Animals. The guidelines for the care and use of all animals as approved by St. Louis University were followed.

In vivo experiments. Timed pregnant Sprague-Dawley rats (term ~21 days) were used for these studies. Maternal and fetal hyperinsulinemia, together with high glucose concentrations, was produced in vivo by infusing glucose ($n = 5$) (controls, $n = 4$, received sterile distilled water infusions) into the mothers (for 5 days; 24% of gestation). Low insulin concentrations with hyperglycemia were produced by streptozotocin treatment ($n = 4$) (controls, $n = 5$, received saline solution injections), resulting in 6 days of hyperglycemia (28% of gestation), as described previously.[20] Briefly 13-day-pregnant rats were administered pentobarbital for anesthesia and underwent cannulation of the external jugular vein. At 24 hours after the surgical procedure, maternal and fetal hyperglycemia with hyperinsulinemia was produced in some rats by administration of a 30% glucose-in-water infusion at a rate of 17 mg/kg/min. The controls, on the other hand, received a sterile distilled water infusion at a similar rate until 18 to 20 days of gestation. Maternal diabetes was induced in 12-day-pregnant rats by intraperitoneal injections of streptozotocin (60 mg/kg), while the controls received saline solution injections alone. Maternal tail vein glucose values were monitored by Chemstrip bG (Boehringer-Mannheim, Indianapolis), 48 hours (14 to 15 days' gestation) after the initiation of the infusions or the streptozotocin treatment. Before removal of the maternal and fetal organs, plasma was obtained from mothers and fetuses (at 18 to 20 days' gestation). The glucose concentrations were determined by the glucose oxidase method of Yellow Springs Instrument Co., Yellow Springs, Ohio,[17] and the insulin concentrations were measured by a radioimmunoassay.[17] Statistical differences between the two groups (treatment versus respective control) were determined by Student's t test. Maternal and fetal brains and livers were obtained at 18 to 20 days' gestation and crude membranes were prepared by differential centrifugation.[21] Membrane protein content was determined by the Bio-Rad assay (Bio-Rad Laboratories, Richmond, Calif.).[22]

Brain cell preparation. Neuron-enriched cultures[23] were prepared from fetal-neonatal rabbits and characterized as previously described.[23] The rabbit was chosen for in vitro studies as the cellular yield is higher and we have extensively characterized the rabbit neuronal cells by immunocytochemistry.[23] The purity of the neuronal cultures was determined to be ~85% by positive staining of cells for the neuron-specific enolase enzyme,[23] while glial contamination was determined by the presence of glial fibrillary acidic protein staining of cells.[23] The neuron-enriched cultures were maintained in 10 ml of a serum-free defined medium, which contained a high D-glucose concentration[19] (3 mg/ml) either with or without porcine insulin (Eli Lilly & Co., Indianapolis) (5 μg/ml) for a period of 5 days. The cells were then washed extensively and scraped with a rubber policeman before homogenization and centrifugation.[24] Protein content in the membrane pellet was determined by the Bio-Rad dye-binding assay.[22]

Iodine 125–insulin–binding assay. Porcine insulin (Eli Lilly & Co.) was iodinated to a specific activity of 100 to 150 μCi and used as a ligand.[25] A ^{125}I-insulin–binding assay with 0.5 mg of membrane protein was carried out as previously described by us.[20] Briefly, ^{125}I-insulin was incubated at 4° C in the presence (nonspecific) or absence of 1×10^{-6} mol/L native insulin along with the membrane and 1% bovine serum albumin in a final volume of 0.5 ml of Hepes buffer, pH 7.8. The bound fraction was separated from the free fraction by centrifugation. The ^{125}I-insulin–bound receptor was cross-linked with 0.1 mmol/L disuccinimidyl suberate for 16 minutes at 4° C.[26] The cross-linked ^{125}I-insulin–receptor complex was solubulized in Laemmli's buffer before the samples were subjected to sodium dodecyl sulfate–polyacrylamide gel electrophoresis.[27] Protein separation was accomplished by use of a discontinuous 5% sodium dodecyl sulfate–polyacrylamide gel system at a constant current of 30 mA per gel. The protein bands were then stained with Coomassie blue, dried, and subjected to autoradiography for at least 48 hours.[27] The autoradiographs were scanned with a Bio-Rad densitometer and the density-area of the band was calculated. The band density-area changes were taken to represent the changes in receptor abundance alone, as a change in receptor affinity has previously not been observed by Scatchard analysis in response to insulin perturbations.[15-17]

Results

A quick screening of maternal glucose concentrations by the Chemstrip bG method at 14 to 15 days' gestation revealed that the maternal glucose infusions (mean ± SEM, 117.5 ± 10.48 vs control of 71.88 ± 4.30 mg/dl; $p < 0.01$) and streptozotocin treatment (190 ± 32 vs a control of 105 ± 5 mg/dl; $p < 0.05$) caused maternal hyperglycemia by 48 hours. The discrepancy between the glucose values of the two control groups is secondary to a relative dilution of the glucose concentrations in the former group by the sterile water infusions.

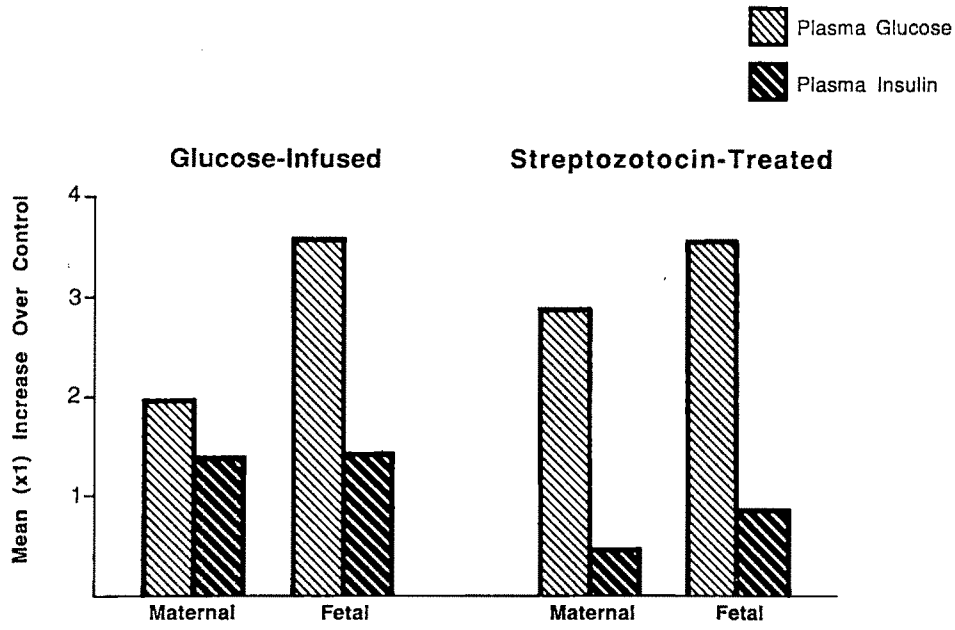

Fig. 1. Plasma glucose and insulin concentrations. Mean increase or decrease in maternal and fetal plasma glucose and insulin concentrations over the corresponding control that was standardized to a value of 1 is shown.

These infusions led to relatively lower control glucose values when compared with those of the control rats, which merely received intraperitoneal injections of normal saline solution.

Fig. 1 demonstrates the mean increase or decrease of plasma glucose and insulin concentrations (at 18 to 20 days' gestation) over a corresponding control that was standardized to 1 for comparison purposes. This standardization was necessary as again the two control values for glucose and insulin were different from each other. Glucose infusions produced a twofold to threefold increase in the maternal (369 ± 79 mg/dl vs a control of 187 ± 7 mg/dl; $p < 0.05$) and a 3.6-fold increase in the fetal (155 ± 25 vs a control of 43 ± 3 mg/dl; $p < 0.01$) plasma glucose levels, respectively. This increase in the plasma glucose level was associated with a 1.5-fold increase in maternal and fetal plasma insulin concentrations. Streptozotocin treatment, on the other hand, while increasing the maternal (317 ± 11 mg/dl; $p < 0.01$) and fetal (214 ± 6 mg/dl; $p < 0.01$) plasma glucose concentrations threefold and 3.6-fold over control (maternal, 109 ± 3 mg/dl; fetal, 60 ± 12 mg/dl), decreased the maternal insulin concentrations to half and the fetal levels to 0.85 of control.

Figs. 2 and 3 represent autoradiographs of the glucose-infused and streptozotocin treatment experiments. Maternal and fetal liver insulin receptor α-subunit (the subunit that binds the hormone) demonstrates a molecular mass of ~135,000, while the maternal and fetal brain receptor is only ~125,000 as observed previously by us.[20] The insulin receptor capacity as determined by the band density-area is decreased in the maternal liver and increased in the fetal liver in response to high circulating insulin concentrations (glucose-infused), while the brain insulin receptor band density-area remained unchanged. In the streptozocin treatment studies hypoinsulinemia in the mother resulted in an increase in the maternal liver insulin receptor band density-area, yet low but normal fetal insulin levels increased the fetal liver insulin receptor band density-area. Again the brain insulin receptor density remained unchanged.

Fig. 4 demonstrates the neuronal insulin receptor. As reported previously, the neuronal insulin receptor, similar to the whole brain, has a molecular mass of ~125,000.[20] The neuronal insulin receptor band density-area akin to that of the whole brain did not change as a secondary result of insulin exposure.

Comment

We have presented evidence to support the fact that long-term maternal and fetal exposure to insulin both in vivo and in vitro, while altering the insulin receptor density-capacity in the liver, fails to do so in the brain, specifically in the neurons. This observation is similar to previously reported results in the adult nonpregnant rat[15, 16] and rabbit fetus in association with acute episodes of hyperinsulinemia.[17] Although a

down-regulation of neuronal insulin receptors was observed in avian embryonic neurons in culture,[18] our studies demonstrate that this insulin responsiveness of the brain insulin receptor does not persist but disappears during late mammalian fetal life. This may be secondary to species differences but more important may be due to the difference in the stages of maturation. The chick embryo represents a rather early stage of development while in the rat and rabbit a later stage, i.e., the third-trimester fetus, was specifically studied. We chose this developmental phase because the growth-promoting effect of insulin has been reported mainly during this period in mammalian tissues including the brain.[7, 8] However, the presence of insulin-induced down-regulation of the early embryonic neuronal insulin receptor may alter the process of neurogenesis and partly mediate the development of neural defects observed in fetuses of diabetic pregnancies.[1]

Insulin receptor (α-subunit) in streptozotocin-treatment studies. *Top panel* demonstrates autoradiographs with insulin receptor bands. **A**, Maternal and fetal liver insulin receptors in streptozotocin *(stz)*—treated and control *(C)* groups are seen. **B**, Maternal and fetal brain insulin receptors in the two groups are seen. *Bottom panel* depicts corresponding densitometric assessment of band area. Control is standardized to 1.

As previously described, the maternal liver insulin receptor was down regulated in response to high insulin concentrations and up regulated as a result of low insulin concentrations.[10, 11] The fetal liver insulin receptor number, on the other hand, was up regulated in both states, i.e., the hyperinsulinemic situation[12, 13] and in association with streptozotocin-induced maternal diabetes.[28] This phenomenon may be due to decreased fluidity of the fetal liver membranes as a result of maternal diabetes,[28] thus resulting in an inability to down regulate surface receptors. There may be other explanations for this phenomenon that have not so far been described, whereby the fetal liver insulin receptor is resistant to insulin-induced down regulation. However, the explanation does not lie in a difference in either the glycosylation[20] or the autophosphorylation[29] of fetal insulin receptors when compared with that of the adult counterpart.

Circulating insulin has been demonstrated to gain access to the cerebrospinal fluid in the adult rat.[4] Al-

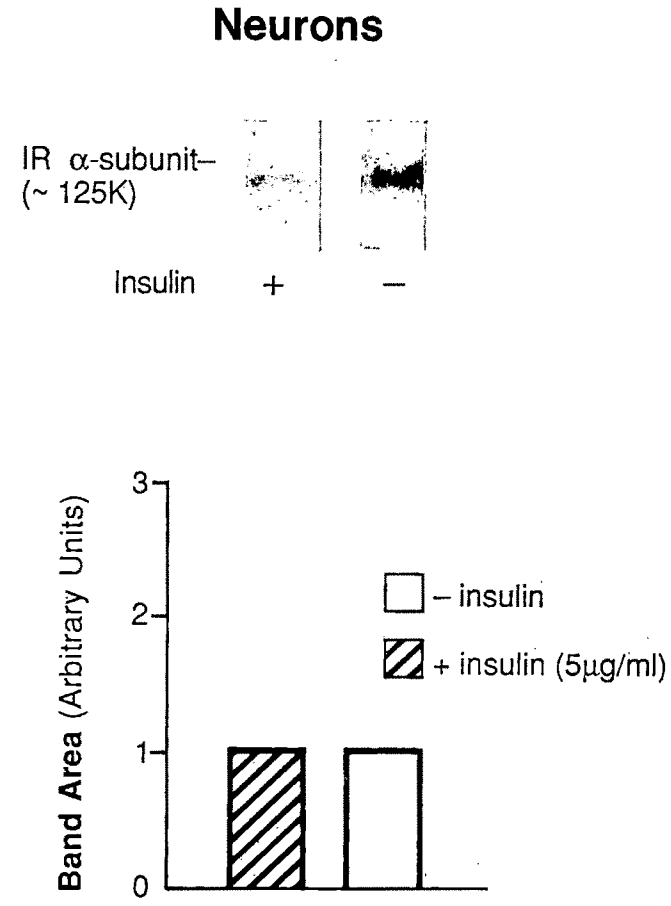

Fig. 4. Neuronal insulin receptors. *Top panel* depicts neuronal insulin receptor band in presence (+) and absence (−) of insulin (total of 50 μg). *Bottom panel* demonstrates corresponding densitometric assessment of band area. Control (−) is standardized to 1.

though short-term perturbations in plasma insulin concentrations are not reflected in the cerebrospinal fluid, long-term changes in the circulating levels of the hormone are reflected in the cerebrospinal fluid in an integrated fashion.[4] Additionally, in the newborn rabbit, labeled insulin injected into the carotid artery gained access to the brain parenchyma.[30] Thus in both our models with hyperinsulinemia and hypoinsulinemia a period of 5 to 6 days is more than adequate to attain parallel changes within the cerebrospinal fluid (and possibly brain parenchyma). Yet long-term exposure of the brain to changes in insulin concentrations failed to alter (down regulate) both maternal and fetal brain insulin receptors. More interesting, however, is the fact that the neuronal cell insulin receptor exposed directly to insulin is resistant as well.

These findings are consistent with the functional significance of these receptors; the liver insulin receptor mediates the traditional effects of insulin such as enhancing the conversion of glucose to glycogen and thereby influencing the glucose homeostasis.[14] The neuronal insulin receptor, on the other hand, mediates unconventional insulin effects such as augmentation of neurite growth,[7] neuronal differentiation,[31] and modulation of neurotransmission[32] while playing no role in neuronal glucose metabolism.[32] An inability of the neuronal insulin receptor to down regulate in response to insulin suggests a protective phenomenon by the cell against perturbations in cerebrospinal fluid insulin concentrations. Recently, we demonstrated that the neuronal cell synthesizes insulin (or an insulin-like substance) as an extrapancreatic source of the hormone.[23] Whether endogenous production of the hormone causes a cellular resistance that results in the inability of the exogenous hormone to down regulate its specific receptor remains unknown.

The physiologic significance of our observation, however, is that in chronically hyperinsulinemic or hypoinsulinemic third-trimester fetuses, while the liver metabolism may be (adversely) altered because of down regulation or up regulation of the insulin receptor, the neuronal cell metabolism is relatively protected, thus allowing neuronal energy balance and functioning to proceed. Whether neuronal growth and differentiation

continue normally in the face of altered circulating insulin concentrations during the first and second trimesters is an issue that requires further investigation in the in vivo mammalian model.

Venous and hepatic vascular responses to indomethacin and prostaglandin E_1 in the fetal lamb

René P. Paulick, MD,[a] Rebecka L. Meyers, MD,[b] Colin D. Rudolph, MD, PhD,[c] and Abraham M. Rudolph, MD[c]

San Francisco, California

Evidence is accumulating that prostaglandins affect the tone of the ductus venosus. Therefore prostaglandins might alter the distribution of umbilical venous return between the ductus venosus and liver. We have examined the effect of indomethacin and prostaglandin E_1 on the vascular resistance of the umbilical-placental circulation, ductus venosus, and liver in 14 chronically instrumented fetal lambs. We found that indomethacin caused a nearly twofold increase in the vascular resistance of both the ductus venosus and liver. Prostaglandin E_1, administered 70 minutes after indomethacin at a dose of 0.41 ± 0.09 (SEM) μg/min per kilogram of fetal weight, decreased umbilical-placental blood flow, increased the vascular resistance of the umbilical arteries and placenta, and reversed the elevation of the vascular resistances of the ductus venosus and liver. Because both indomethacin and prostaglandin E_1 affected the resistances of the ductus venosus and liver to the same extent, it is unlikely that prostaglandins of the E series mediate the change in distribution of umbilical venous return between the ductus venosus and liver during fetal stress. (Am J Obstet Gynecol 1990;163:1357-63.)

Key words: Blood flow, blood pressure, radioactive microspheres, prostaglandins, indomethacin

During fetal development about 40% of the combined ventricular output is distributed to the placenta. Blood returns to the fetus through the umbilical veins to the portal sinus; it may then pass through the hepatic microcirculation or bypass the liver through the ductus venosus. Normally, about half the umbilical venous return passes through the ductus venosus and half through the liver.[1] These proportions change during fetal stress, particularly when umbilical blood flow falls, with a greater proportion of umbilical venous return passing through the ductus venosus.[2-5] The factors that determine the distribution of blood flow between the ductus venosus and liver have not been defined but may involve constriction or relaxation of the ductus venosus.

Evidence is accumulating that prostaglandins affect the tone of the ductus venosus. With the use of rings of ductus venosus, Adeagbo et al.[6,7] showed constriction with indomethacin, a prostaglandin synthesis inhibitor, and relaxation with prostaglandin E_2 (PGE_2) and prostacyclin (PGI_2). A preliminary report of an in vivo study in fetal lambs supported these results.[8] In addition, prostaglandin E_1 (PGE_1), a synthetic analog of PGE_2, has been shown to reopen the closed ductus venosus in newborn lambs.[9] However, none of these studies has measured the actual changes in vascular resistance across the ductus venosus and liver in response to indomethacin and PGE_1.

To determine the influence of indomethacin and PGE_1 on the vascular resistance of the ductus venosus, liver, umbilical veins, umbilical arteries, and placenta in fetal lambs, we measured blood pressure in the fetal descending aorta, extraabdominal umbilical vein, portal sinus, hepatic vein, and inferior vena cava; we also measured blood flow with the microsphere technique. From these data we calculated changes in the vascular resistance of each component of the umbilical-placental circulation.

Material and methods

Surgery and experiments were performed according to the guidelines for the care and use of animals approved by the Committee on Animal Research, University of California, San Francisco. Fourteen mixed-breed Western ewes with time-dated gestation of 122 to 137 days at the time of study (term, 145 days) were fasted 24 to 48 hours before spinal anesthesia was induced with 2 to 4 ml of 1% tetracaine hydrochloride (Ponto-

caine, Winthrop Labs., New York) and they were placed supine on the operating table. Polyvinyl catheters (inner diameter, 0.05 inches) were inserted into pedal branches of a maternal femoral artery and vein and advanced to the descending aorta and inferior vena cava. An intravenous infusion of 0.9% sodium chloride (500 to 1000 ml) was administered to the ewe throughout the procedure. Ketamine hydrochloride, 50 to 100 mg, was injected intravenously as necessary to maintain sedation. With the use of strictly aseptic techniques, the ewe's abdomen was opened in the midline. Anesthesia for the placement of all fetal catheters was induced locally with 0.5% lidocaine hydrochloride and systemically with 15 to 20 mg of intramuscular ketamine. The fetal hind limbs were exposed through a small uterine incision, and polyvinyl catheters (inner diameter, 0.03 inches) inserted in each leg via pedal branches into the infrarenal descending aorta. Through a pedal branch of the femoral vein, a 3.5 F multiple side-hole catheter was advanced centrally so that the tip was at the level of the diaphragm where the ductus venosus and hepatic veins enter the inferior vena cava. Two 3.5 F multiple side-hole catheters were inserted via cotyledonary tributaries into the extraabdominal umbilical vein. The tips of the umbilical vein catheters used for pressure measurements were on average 27 cm distal to the umbilical ring. An amniotic catheter (inner diameter, 0.05 inches) was inserted to lie adjacent to the fetal trunk, and the uterine incision was closed.

A catheter was placed in the portal sinus in eight fetuses. Through a separate uterine incision, the fetal abdomen was exposed and opened and a loop of small intestine isolated. A 3.5 F multiple side-hole catheter was inserted into a mesenteric venous tributary and advanced toward the hilum of the liver until blood withdrawn from the catheter showed increased oxygenation, indicating mixture with umbilical venous blood. When the oxygen saturation of the blood in this catheter matched that of blood in the umbilical vein, the catheter was drawn back slowly until a sharp drop in oxygen saturation occurred. From this point the catheter was then advanced proximally 1 cm. With this approach the catheter tip was reliably located in the portal sinus.

In six fetuses a catheter was placed in either the left ($n = 4$) or right ($n = 2$) hepatic vein. The method has been previously described in detail.[10] Briefly, through a right thoracotomy, the inferior vena cava was punctured through a purse-string suture and a 3.5 F multiple side-hole catheter was advanced ≈3 cm inferiorly into a hepatic vein. Catheter placement in the hepatic vein was confirmed by comparing the oxygen saturation of blood withdrawn from this catheter with that of blood in the umbilical vein and inferior vena cava.

The fetal and uterine incisions were closed, and amniotic fluid lost during surgery was replaced with warm 0.9% sodium chloride. All catheters were filled with heparin (1000 IU/ml) and plugged. The catheters were then brought subcutaneously to the ewe's flank where they were exteriorized and stored in a vinyl pouch. On the day of surgery and each day afterward, the ewe received 2 million IU of penicillin G and 100 mg of gentamicin, half intravenously and half into the amniotic cavity. Vascular catheters were flushed daily with heparin. The position of all catheters was confirmed at dissection.

Fourteen studies, one of each fetus, were performed 2 to 6 days after surgery. Fetal descending aortic, amniotic, and venous pressure levels (extraabdominal umbilical vein, portal sinus, hepatic vein, and inferior vena cava) were measured with carefully calibrated pressure transducers (Statham P23Db, Statham Instruments, Oxnard, Calif.). Pressure levels were recorded continuously on a direct writing recorder (Beckman R612, Beckman Instruments, Palo Alto). Baseline pressure levels were recorded for 2 to 3 hours to obtain steady state conditions, minimize zero drifts, and make calibration adjustments. To eliminate errors as a result of possible zero drift in different transducers, all venous pressure levels were recorded with the same transducer with a ramp of Luer-Lok stopcocks (Vygon, Ecouen, France). Each "set" of venous pressures was obtained within a period of 45 to 60 seconds, and pressure levels were accepted as valid only when amniotic and arterial pressures remained constant during this time. Throughout the experiment, zero levels were checked every 10 to 15 minutes and did not vary >1 mm Hg. Fetal heart rate was measured with a cardiotachometer triggered by the arterial pulse pressure. Amniotic pressure was used as the zero pressure reference.

Control blood samples were withdrawn from the fetal descending aorta. Blood gas and pH levels were measured with a blood gas analyzer (Corning 175, Medfield, Mass.). Hemoglobin concentrations and blood oxygen saturation were measured photometrically in duplicate (Hemoximeter OSM 2, Radiometer, Copenhagen, Denmark). A bolus of approximately 2 million (15.0 ± 0.3 SD) μm microspheres labeled with different isotopes randomly selected from cobalt 57, chromium 51, gadolinium 153, indium 114, manganese 54, niobium 95, tin 113, strontium 85, and zinc 65 (3M Company, St. Paul, and New England Nuclear, Boston) was then injected into the umbilical vein. A reference arterial blood sample was withdrawn from the descending aorta at ≈3.6 ml/min, beginning 10 to 15 seconds before the microsphere injection and lasting 75 to 90 seconds. The volume of blood withdrawn was replaced with an equal volume of fetal donor blood or, if this was not available, with maternal blood. A dose of 0.33 ± 0.07 (mean ± SEM) mg/kg fetal weight indomethacin (Merck, Sharp & Dohme, West Point, Pa.) was then injected into

the umbilical vein. Sixty minutes later, venous pressure levels and blood samples from the descending aorta were obtained and microspheres labeled with different radionuclides were injected into the umbilical vein. After 10 minutes (i.e., 70 minutes after the injection of indomethacin) PGE_1 (Upjohn, Kalamazoo, Mich.) was infused diluted in 0.9% sodium chloride with a Harvard pump at a dose of 0.41 ± 0.09 (SEM) μg/min per kilogram of fetal weight into the umbilical vein for 20 minutes; 15 minutes after beginning the PGE_1 infusion, venous pressure levels and blood samples were obtained and a third set of randomly chosen microspheres was injected into the umbilical vein.

At the end of the study the ewe was killed with an overdose of pentobarbital sodium. The uterus and individual fetal organs were dissected and weighed. All organs were placed in formalin, incinerated at 350° C, ground into a coarse powder, and placed into plastic vials to a uniform height of 3 cm.[11] The vials were counted in a well-type γ-scintillation counter and analyzed with a multichannel (1024) pulse height analyzer (Norland, Ford Atkinson, Wis.). The activity of each isotope in each organ was determined from an analysis method of least squares described previously.[12]

Microspheres injected into an umbilical vein are either trapped in the liver or passed through the ductus venosus to the inferior vena cava. Thus the proportion of umbilical venous return distributed to the liver can be calculated from the counts in the liver divided by the total counts recovered from the fetus and placenta.[1] Subtraction of this proportion from 1 yields the proportion of umbilical venous return that passes through the ductus venosus. Adequate mixing of microspheres in umbilical venous blood has been shown in a previous study in which microspheres labeled with different radionuclides were simultaneously injected into different branches of the umbilical veins.[2] These studies show that the distribution of microspheres injected into one branch of the umbilical vein represents the pattern of distribution of all the umbilical venous blood.

Except for the liver, blood flows to the lower body organs and placenta were calculated from the counts in the organ, divided by the counts in the reference sample, and miltiplied by the reference sample blood flow.[11-13] Umbilical vein-derived blood flow to the left and right lobes of the liver and through the ductus venosus was calculated by multiplying the umbilical-placental blood flow by the proportion of umbilical venous return distributed to each lobe and through the ductus venosus, respectively. Blood flow to the right lobe of the liver was then calculated by adding portal venous blood flow to the umbilical venous flow distributed to the right liver. Finally, total liver blood flow was calculated by adding that of the left and right lobe.

These calculations are made on the basis of previous studies that have shown that the right lobe of the liver receives almost all the portal venous blood and a contribution of umbilical venous blood.[1] The left lobe of the liver and the ductus venosus receive primarily umbilical venous blood. The hepatic arteries contribute <10% of total liver blood flow in the fetus[1,4]; this was considered negligible. Portal blood flow was calculated as the sum of flows to the spleen, pancreas, and gut. Blood flows are expressed as milliliter per minute per kilogram of fetal weight.

Total resistance to umbilical-placental blood flow was calculated from umbilical-placental blood flow and the pressure difference between the descending aorta and inferior vena cava. With the use of the pressure levels measured in the umbilical vein and portal sinus, this total vascular resistance was subdivided as follows: (1) resistance to umbilical-placental blood flow between the descending aorta and umbilical vein, representing the resistance of the umbilical arteries and placental microvasculature; (2) resistance between the umbilical vein and portal sinus, representing the resistance of the umbilical veins; and (3) resistance between the portal sinus and inferior vena cava, representing the combined resistance of the ductus venosus and liver. Individual resistances of the ductus venosus and the liver were then calculated by dividing the pressure difference between the portal sinus and inferior vena cava by the appropriate blood flow levels. In the six fetuses with a hepatic vein catheter, pressure levels measured simultaneously in the hepatic vein and inferior vena cava were not significantly different throughout the experiments. Therefore we used the inferior vena caval pressure level for the above resistance calculations. Values for vascular resistance are expressed as millimeters of mercury per milliliter per minute per kilogram of fetal weight.

Data analysis was performed with a computerized statistical program (Statview II, Abacus Concepts, Berkeley, Calif.). When a normal distribution was present, data are expressed as mean ± SEM. Comparison between the three experimental periods was made by one-way analysis of variance for repeated measurements. Multiple comparison testing was performed only if the analysis of variance first rejected a multisample hypothesis of equal means with $p < 0.05$. Differences between groups were then analyzed with the Scheffé multiple comparison F test. For the abdominal inferior vena caval blood flow and the resistance of the liver, a skewed distribution was shown by box plots. In these two cases, results are expressed as mean ± SEM after eliminating one extreme outlying value; for multiple comparison testing, we used the Friedman test and analyzed differences between groups with the Wilcoxon test with the Bonferroni adjustment. For all tests, $p < 0.05$ was considered statistically significant.

Results

Fetal weight was 3.3 ± 0.2 kg. During the control period, fetal pH, blood gas levels, and hemoglobin concentrations in the descending aorta were within the normal range of values measured in our laboratory (Table I). Indomethacin injection caused no significant changes in these variables. During the PGE_1 infusion, P_{O_2}, oxygen saturation, and pH decreased.

Fetal heart rate was 186 ± 6 beats/min at control, 202 ± 9 beats/min 1 hour after indomethacin, and 184 ± 10 beats/min during the subsequent PGE_1 infusion; these changes were not significant. Indomethacin significantly increased pressures in the descending aorta, extraabdominal umbilical vein (catheter tip on average 27 cm distal to the umbilical ring), and portal sinus, whereas inferior vena caval pressure was not changed (Table II). All pressures returned to control values during the PGE_1 infusion. In the six experiments in which pressures were measured simultaneously in the inferior vena cava and a hepatic vein, there was a small but insignificant pressure difference between these two sites (0.5 ± 0.2 mm Hg) during all experimental periods.

During the control period the difference in pressure between the descending aorta and extraabdominal umbilical vein, which represents the pressure drop across the umbilical arteries and placenta, was 36.2 ± 1.0 mm Hg (Table II). The difference in pressure between the extraabdominal umbilical vein and the portal sinus, which represents the pressure drop along the umbilical veins, averaged 5.5 ± 0.9 mm Hg, and that between the portal sinus and inferior vena cava, which repre-

sents the pressure drop across the ductus venosus and liver, was 1.7 ± 0.2 mm Hg. Indomethacin increased the pressure difference between the portal sinus and inferior vena cava significantly by 76%. During the PGE_1 infusion all pressure differences had returned to control values.

Compared with the control period, indomethacin did not change umbilical-placental, hepatic, ductus venosus, or abdominal inferior vena caval blood flow (Table III). Compared with the flows measured after indomethacin, the PGE_1 infusion decreased umbilical-placental blood flow significantly. Neither indomethacin nor PGE_1 changed the proportion of umbilical venous return that passed through the ductus venosus or the left or right lobe of the liver.

During the control period total vascular resistance to umbilical-placental blood flow averaged 0.239 mm Hg/ml per minute per kilogram of fetal weight. Of this total resistance, the umbilical arteries and placenta accounted for 84%, the umbilical veins 12%, and the ductus venosus and liver 4%. Indomethacin increased the combined vascular resistance of the ductus venosus and liver almost twofold (Table IV). The individual resistance of the ductus venosus increased 75% and that of the liver increased 65%. Furthermore, the vascular resistance of the right and left lobes of the liver increased to the same extent. Infusion of PGE_1 completely reversed this indomethacin effect of the vascular resistance of the ductus venosus and liver. However, total resistance to umbilical-placental blood flow increased as a result of an increase in the resistance of the umbilical arteries and placenta.

Comment

The distribution of the umbilical venous return between the ductus venosus and liver is altered during fetal stress; the proportion of umbilical venous blood that passes through the ductus venosus increases, whereas that to the liver decreases.[2-5] However, the mechanism responsible for this change in distribution of umbilical venous return is not known. Adeagbo et al.[6,7] showed in vitro that indomethacin, a prostaglandin synthesis inhibitor, constricted the ductus venosus, whereas both PGE_2 and PGI_2 resulted in relaxation. Blood concentrations of PGE were found to be elevated during chronic fetal hypoxemia.[14] Thus pros-

taglandins could be important in the regulation of the tone of the ductus venosus during fetal development. To examine this hypothesis we studied the effect of indomethacin and PGE_1, a synthetic analog of PGE_2, on the vascular resistance of the ductus venosus and liver in chronically prepared fetal lambs.

Indomethacin did not change umbilical-placental blood flow[15, 16] or the proportion of umbilical venous return distributed to the ductus venosus and liver. Thus ductus venosus and liver blood flows were unchanged. These results conflict with those in a preliminary report that suggested that indomethacin decreases ductus venosus blood flow in fetal lambs, but no data on umbilical-placental or ductus venosus blood flows were provided.[8]

Indomethacin had no effect on the vascular resistance of the umbilical arteries, placental vasculature, or umbilical veins. Indomethacin increased the vascular resistance of the ductus venosus almost twofold; this effect was reversed by PGE_1. Thus the ductus venosus sphincter appears to be under the control of a relaxing prostaglandin in the fetus. According to Coceani,[17] this relaxing prostaglandin is PGE_2 or PGI_2. However, this effect is not specific for the ductus venosus because hepatic vascular resistance increased to about the same extent as that of the ductus venosus after indomethacin. The site of the increase in hepatic vascular resistance has not been delineated. On the basis of anatomic studies, sphincters have been described presinusoidally at the portal venous-sinusoidal junction and postsinusoidally at the sinusoidal-central vein junction and in the hepatic veins.[18, 19] On the basis of physiologic studies, Lautt et al.[20, 21] proposed that the major site of portal vascular resistance resides in small hepatic veins, beyond the sinusoidal-central vein connection. We were not able to detect any constriction in the large hepatic veins, but constriction may occur in small hepatic veins with a diameter of 1 to 2 mm.

The fact that the vascular resistance of both the ductus venosus and liver increases with indomethacin and decreases with PGE_1 indicates that, in the fetus, prostaglandins are important in maintaining a low resistance to umbilical venous and portal venous return. This effect appears to be similar to that of PGE_2 on the ductus arterious.[17] However, because indomethacin and PGE_1 had no differential effect on the ductus venosus and liver, it is evident that prostaglandins of the E series do not mediate the change in distribution of umbilical venous return between the ductus venosus and liver during fetal stress.

The effect of indomethacin on the ductus venosus was not dramatic and ductus venosus blood flow was well maintained. This observation does not support the proposal that the postnatal decrease in PGE blood concentrations[22] would play a significant role in closing the ductus venosus after birth.[17]

McLaughlin et al.,[15] on the basis of physiologic studies, reported that indomethacin results in vasoconstriction of the umbilical-placental circulation. However, this vasoconstrictive effect was observed immediately after indomethacin injection and was sustained for only 10 minutes. Our results show no change in the vascular resistance of the umbilical arteries, placental vasculature, or umbilical veins 60 minutes after indomethacin injection. As was shown by Naden et al.,[23] blood concentrations of PGE_2 do not decrease immediately after indomethacin. The same authors suggested that indomethacin has immediate vasoconstrictive properties that are independent of the inhibition of prostaglandin synthesis. In support of this, our group found that indomethacin produced an immediate rise in arterial blood pressure in fetal lambs pretreated with meclofenamate, a prostaglandin synthesis inhibitor (M. Heymann, personal communication).

As has been observed previously, PGE_1 decreased umbilical-placental blood flow.[24, 25] This fall in blood flow was a result of an increase in the vascular resistance of the umbilical-placental circulation. The site of this increased resistance has not been determined. It was not in the major umbilical veins, and thus must have been either in the umbilical arteries or the placental microvasculature. On the basis of in vitro studies, PGE_1 may cause constriction of the umbilical arteries.[26, 27]

In conclusion, we showed that prostaglandins maintain a modest degree of relaxation of the ductus venosus and hepatic microcirculation during fetal development but are not responsible for the redistribution of umbilical venous return between the ductus venosus and liver during fetal stress.

We gratefully acknowledge the skillful technical assistance of Christine Roman, Roger Chang, Bruce Payne, and Carl McWatters that made the completion of this project possible. We also acknowledge the editorial assistance of Paul Sagan.

Correction

In the article by Fong et al., "Fetal thoracic circumference: A prospective cross-sectional study with real-time ultrasound" (Am J Obstet Gynecol 1988;158:1154-60), in the last paragraph on page 1158, the sentences "The ratio chest circumference/abdominal circumference was found to be constant across gestation. A 95% confidence interval for predicting this ratio for a given gestational age is given by 0.91 ± 0.046" should have been "The ratio chest circumference/abdominal circumference was found to be constant across gestation. A 95% confidence interval for predicting this ratio for a given gestational age is given by 0.88 ± 0.13."

LETTERS TO THE EDITORS

Definition of fetal asphyxia

To the Editors: I enjoyed reading the article on umbilical blood acid-base studies in the March 1990 issue (Johnson JWC, Richards DS, Wagaman RA. The case for routine umbilical blood acid-base studies at delivery. AM J OBSTET GYNECOL 1990;162:621-5). I concur with their opinions. I do have one question: How do they define "fetal asphyxia"? They point out that acid-base measurements are superior to Apgar score, fetal heart rate monitoring, neurologic development, and meconium staining in diagnosing asphyxia, but how low does the pH have to be? Below 7.20? Below 7.00? Is a buffer base of <34 mmol/L sufficient? On page 622 they state that fetal asphyxia is "hypoxia and acidosis." I agree. How low does the Po_2 have to be? <22 mm Hg? Is an infant with a Po_2 of 0 automatically suffering from asphyxia? They state that "umbilical blood acid-base studies are the only scientific, objective measure of fetal asphyxia . . ." What is the scientific, objective acid-base definition of asphyxia?

Reply

To the Editors: We appreciate Dr. Clark's interest in our article. His questions of how one defines "fetal asphyxia" and "what is the scientific, objective acid-base definition of asphyxia" are important ones. But they are not easily answered. There is no official consensus as to the definition of asphyxia. *Dorland's Illustrated Medical Dictionary,* twenty-sixth edition, 1985, indicates that the Greek derivation of asphyxia means "a stopping of the pulse." Asphyxia is defined as "a condition due to lack of oxygen in respired air, resulting in impending or actual cessation of apparent life." *Stedman's Medical Dictionary,* twenty-fifth edition, 1990, offers a less severe interpretation of asphyxia. This dictionary defines asphyxia as "impaired or absent exchange of oxygen and carbon dioxide on a ventilatory basis; combined hypercapnia and hypoxia or anoxia." These contemporary medical dictionaries provide two very different definitions. Considering the ambiguities of the term "asphyxia," it's not surprising that there are no universally accepted pH, Po_2, or base deficit cutoff values defining its presence. Such cutoffs by necessity would be arbitrary, similar to defining anemia on the basis of packed red blood cell volume. One solution is the utilization of a degree of acidosis and hypoxia represented by 2 SDs below the mean or below the fifth percentile. (On the basis of elective cesarean sections at our institution the mean −2 SDs for umbilical artery values are: pH 7.21, base deficit −4 mEq/L, and oxygen tension 8.0 mm Hg). Another possible definition, as suggested by Dr. Clark, would be a buffer base of <34 mmol/L, cited by Low as the degree of acidosis associated with an increased risk of neurologic abnormality.[1] This would be our preference for present-day usage.

But there are very few other studies available concerning the clinical significance of birth acidosis and hypoxia. Ideal end-points for defining "severe acidosis" or "severe hypoxia" will be those that help to distinguish neonates who have a high risk of long-term complications from those with a favorable outlook. As cord blood acid-base analysis becomes more widely used, we are confident that clinically useful end points will be established.

Cocaine effects on fetal behavioral state

To the Editors: We read with great interest the article by Hume et al. (Hume RF Jr., O'Donnell KJ, Stanger CL, Killam AP, Gingras JL. In utero cocaine exposure: Observations of fetal behavioral state may predict neonatal outcome. AM J OBSTET GYNECOL 1989;161:685-90). We agree in theory with their hypothesis that abnormal neonatal behavioral state organization may be caused by in utero cocaine effects and that the neonatal abnormalities may be predated, and possibly predicted, by fetal behavioral state abnormalities. We have difficulty, however, in how their conclusions are reached. They describe their "fetal neurobehavioral profile," a rather elegant and painstaking examination that permits assessment and recording of the components of fetal behavior (fetal heart rate variability, breathing, gross body movement, and eye, chin, and mouth movement). Their assessment includes undisturbed organization and regulation as well as fetal self-regulation after acoustic stimulation. They define organization and regulation as "the coordination of related components of fetal behavior in a stable yet responsive state" and describe two such states, active sleep (rapid eye movements, chin motion, breathing, and reactive heart pattern) and quiet sleep (no eye movements, chin motion, or breathing with a nonreactive heart rate pattern). These states appear similar to, if not synonymous with, fetal states 2F and 1F, respectively, as described by Nijhuis et al.[1] The investigators then report fetal state disorganization, defined in the discussion as a lack of coincidence of the behavioral state components or delay in their integration, in 13 of the 20 fetuses serially evaluated in utero.

We have several questions regarding their definition of disorganization. Does it require total dissociation of the components of either or both of the fetal states

described during the entire examination, failure to maintain the stable association for a minimal portion of the examination, or failure to reorganize after the acoustic stimulation? Did meeting this definition during one of the serial evaluations place the fetus in the "disorganized fetal state" category, or did this require disorganization during all the examinations? How many examinations were performed, and over what range of gestation? How long were the examinations? By what gestation was regulation considered delayed?

In addition, there is some question as to what is normal, since a normal drug-free group was not evaluated with the neurobehavioral profile. In Nijhuis et al.'s original work,[1] before 38 weeks, coincidence, or simultaneous occurrence, of 1F and 2F state parameters occurred only 55% to 65% of the entire observation time, with the observation period lasting 112 minutes on the average. They suggested that these periods of coincidence occurred by chance and did not represent organized behavioral states because of the lack of simultaneous change of the state variables. Only with the synchronization of these changes, which developed around 36 to 38 weeks, could true behavioral states be defined. One can see how a preterm fetus, without periods of coincidence of parameters a considerable portion of the time, might be at risk for being classified as "disorganized." This is especially true if the fetus is delivered preterm, as were 25% of the fetuses in the study of Hume et al.

Further clarification of the definitions of "organized" and "disorganized" fetal states, as well as comparison with the fetal neurobehavioral profiles and neonatal outcomes of drug-free controls, would greatly enhance this investigation of the effects of cocaine on the developing central nervous system.

Reply

To the Editors: The questions raised by Drs. Tabor and Soffici are insightful criticisms of our work. The issues addressed point out the potential for confusion concerning the terminology used to define the abnormal fetal behavior observed in our cocaine-exposed subjects. The pioneering work by Prechtl, Nijhuis, and Arduini and their colleagues (references 8, 9, 12, 14, and 15 of our article) were used in the formulation of our tool. The classification of fetal behavioral states follows that of Nijhuis, as stated. Our study design involved serial ultrasonographic observations (four to eight per subject) of at least 30 minutes' duration during the course of prenatal care. We scored the behavior observed from 28 weeks on to term. The fetal behavior observed included the acquisition and coordination of components of behavior into the defined states, as described by Nijhuis, and the ability and character of fetal reaction to acoustic stimulus, as well as atypical behavior not observed in normal subjects or described by others. Delay of state organization was scored as abnormal if stable state regulation failed to be appreciated by term (>38 weeks).

The confusion of terminology is significant, and Drs. Tabor and Soffici are entitled to a clarification of our use of "organized" and "disorganized." Normally organized and regulated fetal behavior follows the synchronization of components into stable states by 36 to 38 weeks of gestation. The "disorganized" classification applied to fetuses who had delay of organization, bizarre or atypical behavior, or disrupted behavior in response to stimulation. Three fetuses exhibited sustained hyperpnea plus lack of stable state organization, three fetuses exhibited recurrent yawning and abnormal response to stimulation, and three fetuses were hypertonic and hyperirritable, while four were never observed to attain organized state behavior by term gestation. The atypical fetal behaviors were present in those infants scored as being more severely affected as neonates.

The fetal response to stimuli mimics the "all-or-none" or "wired" neonate born with active cocaine intoxication. These neonates are very difficult to arouse, but once so they are very difficult to console. Bradycardia, ballistic fetal activity, and lack of habituation in response to acoustic stimulation were the fetal antecedents to such abnormal neonatal neurobehavior. We have shown our video recordings to many observers of various levels of ultrasonographic or neurobehavior sophistication and all agree in scoring the abnormal cases—the behavior really looks unusual. The need for a prospective study with normal control subjects is apparent and is under way. The use of video recording to score the fetal behavior affords a blinded evaluation to address the criticism of the subjective nature of this interpretation. The results of a larger-prospective longitudinal cohort study are needed to validate the fetal neurobehavioral profile's usefulness and reliability in a clinical setting.

I appreciate the interest in our work.

Preeclampsia—An endothelial cell disorder plus "something else"?

To the Editors: We enjoyed the article by Roberts et al. (Roberts JM, Taylor RN, Musci TJ, et al. Preeclampsia: An endothelial cell disorder. AM J OBSTET GYNECOL 1989;161:1200-4). This work brings up to date the ideas of Page[1] (he also worked in San Francisco) and Beker.[2] Their concept was one of uteroplacental ischemia as the underlying pathophysiologic characteristic of preeclampsia. We agree with the idea that the clinical

syndrome of preeclampsia arises when placental perfusion is poor. In some instances there may be underlying vascular or autoimmune disease.[3, 4] We suggest that in many primigravid women the poor placental perfusion resulting from a failure of secondary trophoblast invasion seems to be related to a genetic,[5, 6] or possibly immunogenetic,[7] susceptibility. Roberts et al. do not offer any explanation either for the fact that preeclampsia is commonest in primigravid patients or for the protective effect of a first pregnancy.[8] Does this not suggest an involvement of the immune system,[9] and if so, how?

Reply

To the Editors: Drs. Liston and Kilpatrick correctly point out that our hypothesis extends the role of reduced placental perfusion in the development of the multisystemic syndrome of preeclampsia, a concept originally proposed by the late Professor E. W. Page of this department. Our proposal provides a rationale for the communication of this abnormality in the intervillous space to the many organ systems involved in the syndrome. As pointed out, we feel that endothelial cell injury-activation by an agent(s) produced by poorly perfused trophoblast could explain the systemic abnormalities observed in preeclampsia. Our hypothesis does not differentiate the several causes of reduced perfusion but predicts that they converge to a common pathway, resulting in the production of this bioactive agent(s).

It was not our purpose to explain how this reduced perfusion is initiated in first-pregnancy preeclampsia. We, as others, unfortunately have no direct information to identify the inciting pathogenetic event in this enigmatic disease. As Drs. Liston and Kilpatrick have demonstrated, there is good evidence that the "something else" described in their letter involves a combination of genetic and immunologic factors.

We feel strongly that any candidate as the intiating cause(s) of preeclampsia must account for reduced trophoblastic invasion, genetic predisposition to the disorder, and the protective effect of exposure to paternal antigens, usually by a previous pregnancy. These phenomena may derive sequentially from the same primary process. For example, the immunogenetic dissimilarity of mother and father, or mitigation of maternal immune "aggression" by previous exposure to paternal antigens, could influence the production of factors (e.g., blocking antibodies, activators of suppressor cells, etc.) that immunologically protect the trophoblast. If these factors are not present in a requisite amount, trophoblastic invasion may be retarded as part of an allogeneic rejection phenomenon. Alternatively, it is possible that independent mechanisms interact to produce preeclampsia. In this scenario a genetically determined abnormality of trophoblast function reducing placental invasiveness might lead to preeclampsia only in the first pregnancy because it compounds a subtle form of the immunologic compromise proposed above. There are obviously numerous other combinations of independent factors (including preexistent microvascular disease) that could converge to generate the syndrome.

Recent advances in our understanding of the fetal-maternal interface, such as the recognition of unique placental major histocompatibility antigens[1] and the characterization of enzymes involved in trophoblastic invasion,[2] should accelerate our understanding of the complexities of normal and abnormal placentation and ultimately will allow the precise identification of "something else."

Possible therapeutic applications of cordocentesis

To the Editors: We read with interest the journal articles by Drs. Economides and Nicolaides et al. concerning antenatal detection of different metabolic disturbances in small-for-gestational-age (SGA) fetuses in samples obtained by cordocentesis.[1-4] The data provided by these authors suggest reduced glucose supply as a reason for reduced growth,[1] and show lower fetal insulin/glucose ratio,[2] and elevated fetal glycine/valine ratio,[3] in SGA fetuses. Most recently they showed that fetal hypertriglyceridemia may be used as a marker for hypoxemia in SGA fetuses.[4]

Intrauterine growth retardation is second only to prematurity in its association with perinatal morbidity and mortality. It may well be time to rekindle interest

in potential clinical application of cordocentesis—namely hyperalimentation as alluded to briefly by Weiner.[5] Because of its invasiveness and concern for infection and possible bleeding, this procedure may be of importance in the management of only a limited group of very premature SGA fetuses caused by uteroplacental insufficiency. Inasmuch as these fetuses often have reduced fetal movements, the ease of this procedure might be enhanced.

Yet to be defined, probably with animal models, are the frequency and specific nutrients that would benefit these fetuses. Thought might be given to a chronic indwelling silastic catheter for continuous nutrition access similar to the Hickman catheter widely used for total parenteral nutrition.

Another therapeutic potential of cordocentesis could be direct administration of steroids to enhance fetal pulmonary maturation. This would bypass the placenta, thus possibly shortening the 12 to 14 hour period that current maternal intramuscular treatment requires before beneficial changes are noted. We would be very interested to learn the above authors' views on these potential clinical therapeutic applications that may widen the current therapeutic uses of cordocentesis.

Serum levels of interleukin-2 and tumor necrosis factor-α in women with recurrent abortion

To the Editors: From an immunologic point of view a certain part of recurrent abortions must be considered as a host-versus-graft reaction of the mother against the fetus. Inasmuch as elevated interleukin-2 levels were found during pregnancy[1] and elevated tumor necrosis factor-α levels were found during acute rejection crisis of allotransplants,[2] we determined levels of interleukin-2 and tumor necrosis factor-α in women with recurrent abortions. During weeks 6 and 14 of pregnancy in 92 women with at least three abortions, 42 pregnant women without any complications, and 28 healthy nonpregnant controls, serum samples were taken and analyzed by a radioimmunoassay (IRE Medgenix, Belgium), allowing the detection of 0.1 ng/ml tumor necrosis factor-α and 0.5 unit interleukin-2 per milliliter. Statistical analysis was performed with the Student t test.

We found an increase in tumor necrosis factor-α serum levels ($p < 0.05$) and a decrease in interleukin-2 serum levels ($p < 0.05$) in women with recurrent abortion compared with women with normal pregnancies (Table I). In 52% of women with recurrent abortion but in only 24% of normal pregnant women no interleukin-2 serum levels could be detected. As far as it could be considered by our study, no differences concerning age or number of pregnancies could be observed.

In accordance with these results one can presume that disturbances of maternal immune tolerance of the fetus in the meaning of rejection could be observed by increased tumor necrosis factor-α serum levels. Low serum levels of interleukin-2 in women with recurrent abortion could be associated with a lack of T and B cell growth, promoting effects that probably lead to insufficient induction of a pregnancy, protecting maternal immune response.

What is birth asphyxia?

To the Editors: We read the article by Thorp et al. (Thorp JA, Sampson JE, Parisi VM, Creasy RK. Routine umbilical cord blood gas determinations? AM J OBSTET GYNECOL 1989;161:600-5.) with interest. This has long been a concern of ours.[1] We believe intensive investigation of cord-blood acid-base findings will substan-

Table I. Tumor necrosis factor-α and interleukin-2 serum levels in women with recurrent abortions

Group	*No.*	*Interleukin-2 (U/ml) (mean ± SD)*	*Tumor necrosis factor-α (ng/ml) (mean ± SD)*	*p Value*

Recurrent abortion	92	0.5 ± 0.74	15.8 ± 14.2	0.05

tially assist in unraveling the mysteries of neonatal physiology and will also assist in the legal arena by elucidating cause and effect of subsequent infant neurologic outcome and by clarifying the result of actions by the medical practitioner.

We were somewhat disturbed by the use of the term *birth asphyxia*. What is birth asphyxia? The authors did not define it, yet make statements such as ". . .acidemia is the most sensitive indicator of birth asphyxia at the time of delivery" and ". . .umbilical cord pH is also useful in ruling out the diagnosis of birth asphyxia in the depressed newborn." Can it be diagnosed only with a pH? How can one rule out a diagnosis if it is not defined?

Asphyxia literally means "a stopping of the pulse."[2] In common usage it implies suffocation, a lack of oxygen, and probably an increase in carbon dioxide tension. That definition was sufficient until blood gas monitoring became available, but is it good enough now? Can asphyxia be present without hypercarbia? Is an anoxic infant necessarily acidemic? The definition of asphyxia that we prefer is "acidosis, hypoxia and hypercarbia."[3] Granted, there are rare instances in which hypoxia could be present without hypercarbia. Actually, all infants are asphyxiated at birth (acidotic, hypoxic, hypercarbic)! The question is what degree of physiologic derangement must be present to cause depression (Apgar score <7)? The authors defined a normal umbilical artery pH as the mean minus 2 SD (the lower limit of normal would then be 7.10). A pH of 7.10 would seem to be a very low finding indeed, and yet be considered normal.

The fact that a majority of the depressed infants had a normal pH (77.8%) and 2.1% of the vigorous infants exhibited umbilical artery acidemia supports the notion that the Apgar score should be used as it was intended—to identify the neonate that needs resuscitation; it should and must never be used as an objective evidence of asphyxia. Again, the finding that the majority of the depressed infants had a normal pH makes one wonder about the sensitivity of pH as a test.

Birth asphyxia is a term that we believe should be discarded. Thorp et al. probably did not define it for good reason—it is probably impossible and undesirable to define in these days of greater precision. In the past, whenever an infant was born in a depressed state, the child was said to be experiencing birth asphyxia. No more. Drs. Silverman[4] and Yeomans[5] do not even use the term *birth asphyxia* (except in their references), and Dr. Page[6] used it sparingly.

We urge Drs. Thorp et al. to either define the term (can pH alone be used?) or abandon it (except in a historical sense).

Reply

To the Editors: We appreciate the authors' interest in our research. It seems rather naive to hope that the term *birth asphyxia* will disappear. Birth asphyxia is variously defined by numerous authors as you point out. It may be defined as acidemia, hypercarbia, and hypoxia.[1] On the other extreme, birth asphyxia may be more rigidly defined to include biochemical criteria (hypoxia, hypercarbia, acidemia) and clinical criteria (birth depression and end-organ evidence of hypoxic damage in the newborn period e.g., early neonatal seizure, renal or cardiac dysfunction).[2] Birth asphyxia, by anyone's definition, at the very least must include acidemia. A pH ≤2 SD below the mean for a population is a satisfactory definition for acidemia. Then, an umbilical cord arterial Ph of ≤7.10 is a reasonable cut-off according to the larger studies[3,4] and certainly is consistent with the observation that the typical neonatal sequelae of birth asphyxia rarely occur at a pH above this value.[5]

The following statement: "the finding that the majority of the depressed infants had a normal pH makes one wonder about the sensitivity of the pH as a test," suggests that the authors have missed a very important point. If the pH is testing for neonatal depression then certainly it is insensitive. However, the pH is not testing for neonatal depression. The pH is testing for birth asphyxia, and it is extremely sensitive because it has no false-negative results (i.e., birth asphyxia does not occur in the presence of a normal pH). Umbilical cord blood pH is not specific because it has a very high false-positive rate (i.e., the majority of babies born with cord blood acidemia develop normally).[6] The finding that the majority of depressed infants had a normal pH should not make one wonder about the sensitivity of pH as a test; rather, it underscores the important fact that there are many causes of neonatal depression other than birth asphyxia (e.g., drugs, trauma, aspiration of pharyngeal secretions, neonatal manipulation, congenital anomalies, antepartum fetal insults, and prematurity).

Embryo migration responsible for ectopic pregnancies

To the Editors: We read with interest the case reported by Weyerman and colleagues (Weyerman PC, Verhoeven AThM, Alberda ATh. Cervical pregnancy after in vitro fertilization and embryo transfer. AM J OBSTET GYNECOL 1989;161:1145-6.). The authors suggest that manipulation of the cervical canal, as in embryo transfer, is important in the etiology of cervical pregnancy after in vitro fertilization. We believe that embryo migration, rather than cervical manipulation, is responsible for the different forms of ectopic and heterotopic pregnancies in patients at high risk for ectopic implantation.

We have reported a case of cervical pregnancy after gamete intrafallopian transfer,[1] which involves no cervical manipulation. With regard to management of the cervical pregnancy, the confirmation of the diagnosis was made late in the pregnancy, thereby making its termination more difficult and hazardous. Therefore the authors allowed the pregnancy to continue, a situation that finally caused hysterectomy to become necessary with loss of reproductive function.

We believe that ultrasonography, particularly transvaginal, will enable early diagnosis of cervical pregnancy after in vitro fertilization or gamete intrafallopian transfer. Once the diagnosis is confirmed, termination of the pregnancy surgically, as in our case,[1] or with methotrexate[2] should be offered to the patient because the risk of hemorrhage is much higher after 8 weeks' gestation.

Responsibility expands to extended family members

To the Editors: Neonatal alloimmune thrombocytopenia, the platelet equivalent of hemolytic disease of the newborn, is a result of maternal antiplatelet antibodies formed against incompatible fetal platelet antigens.[1-5] At least 80% of cases are a result of a lack of the PL-A1 antigen on maternal platelets, which is present on the paternal and affected infant platelets.[2, 6] Although much about this entity is not well understood, it occurs in 1 of 2000 to 1 of 5000 live births, with high rates of morbidity and mortality from the intracranial hemorrhage that occurs in 10% to 40% of the affected infants.[1-7] Because 25% to 50% of the often severe intracranial hemorrhages may occur antenatally,[3-4] current efforts have been expanded to include in utero treatment as well as postnatal intervention.[1, 3, 4, 6] The extremely high risk (>85%) of subsequent pregnancies also being affected underlines the importance of correct diagnosis of the infant, with appropriate family counseling and education.[1, 2]

An inquiry from the mother of one of our recent neonatal intensive care unit graduates diagnosed with neonatal alloimmune thrombocytopenia has highlighted our responsibility to obtain a complete family pedigree and offer genetic counseling and appropriate platelet screening to extended family members of such infants. In this case, the pregnant maternal aunt of the affected infant requested information regarding the chances of her unborn child being affected with neonatal alloimmune thrombocytopenia. Information regarding the disease manifestations and risks to future pregnancies had been discussed with the parents of the index case at the time of diagnosis. However, formalized genetic counseling had not been offered to extended family members.

Some sources recommend obtaining a family pedigree to identify possible PL-A1 antigen-negative platelet donors for future affected infants.[2] The few references that recommend family pedigree and complete platelet testing of all female relatives of the affected infant's mother to identify more women at risk of delivery of an infant with neonatal alloimmune thrombocytopenia are found mainly in the hematologic literature.[6] Because this literature is not generally read by obstetricians, perinatologists, and neonatologists, it was deemed pertinent to alert these medical care providers to the need for family pedigree-targeted platelet antigen testing and genetic counseling in families of infants with neonatal alloimmune thrombocytopenia.

Current research on neonatal alloimmune thrombocytopenia—its cause, clinical course, and antenatal and postnatal treatment—indicates that both antenatal and immediate postnatal treatment may considerably lessen the morbidity and mortality rates of this disorder.[1-4, 6, 7-9] For this reason, we who have direct contact with families of such infants should make extra efforts to identify all females at risk of the delivery of an affected infant.

Does prophylactic amnioinfusion make a difference?

To the Editors: I read the recent article by Strong et al. (Strong TH, Hetzler G, Paul RH. Amniotic fluid volume increase after amnioinfusion of a fixed volume. Am J Obstet Gynecol 1990;162:746-8) with great interest.

I do have some questions about the article. First, why did they feel the need to warm the normal saline solution to 37° C? Miyazaki and Taylor[1] noted that the blood warmer "proved to be unnecessary as long as the infusion rate was limited to 10 to 15 ml per minute."

Second, the authors state, "the mean change in amniotic fluid index for those with preinfusion amniotic fluid index values of >5.0 cm (n = 15) was 4.0 ± 0.8 cm." Why would they amnioinfuse patients who do not meet the criteria of oligohydramnios[2]? Moreover, both Rutherford et al.[3] and Sarno et al.[4] showed adverse intrapartum outcome among patients with amniotic fluid index values ≤5.0 cm, not ≥5.0 cm.

Third, and most important, does prophylactic saline solution amnioinfusion among patients with amniotic fluid index values ≤5.0 cm decrease the incidence of recurrent severe variable fetal heart rate decelerations and the associated morbidity of cesarean section for fetal distress?

Suneet P. Chauhan, MD

Reply

To the Editors: We appreciate the attention and comments directed to our manuscript by Dr. Chauhan.

During our study the infusion rate approached 20 ml/min, thus exceeding Miyazaki and Taylor's maximum recommended rate for infusion of room temperature saline solution. When the amnioinfusate bottle is held 3 to 4 feet above the infusion catheter tip, as it is during most amnioinfusion procedures, the rate of infusion will be 20 ml per minute.[1] Therefore it can be expected that a significant number of women who receive gravity-flow amnioinfusion will exceed the "15 ml rule" and thereby be at increased risk if room temperature saline solution issued. Whereas slower infusion rates can be used, the initial bolus of fluid should be infused relatively rapidly to be effective. If the amnioinfusate bag is held <3 feet above the catheter tip, the rate of amnioinfusion may be too slow to have clinical utility, especially in the setting of severe variable fetal heart rate decelerations or bradycardia. Moreover, reversal of flow through the infusion catheter can occur if the saline solution bag is held so low that intrauterine pressure exceeds that of the incoming saline solution.

To answer the second question, our study protocol for prophylactic amnioinfusion stipulated that each subject was to receive infusion until an amniotic fluid index of at least 8 cm was obtained. Rutherford and associates[2] showed that intraobserver and interobserver error in determining the amniotic fluid index can be as large as 2 cm. An amniotic fluid index ≥8 cm was chosen as a goal because it was above the 5 cm "at risk" level and well outside the range of measurement error. As amnioinfusion appears to be a relatively safe procedure, augmenting the amniotic fluid index to 8 cm likely does no harm and provides an extra margin of safety against intrapartum leakage. Despite this, an amniotic fluid index of 8 cm falls well below the mean for third-trimester gestations.[3, 4]

Does prophylactic amnioinfusion make a difference? Clearly. In a randomized clinical trial of 60 laboring women with amniotic fluid index values ≤5 cm, the amnioinfused group had significantly lower rates of meconium passage, severe variable decelerations, end-stage bradycardias, and operative intervention for fetal distress.[5] In addition, significantly higher umbilical arterial pH values were noted in the infusion group.

As Dr. Chauhan points out, Sarno and associates[6, 7] have suggested that the laboring gravida with an amniotic fluid index ≤5 cm is at significantly increased risks of adverse fetal outcome. Combination of early

intrapartum amniotic fluid index assessment with prophylactic amnioinfusion might favorably impact the outcome of oligohydramnic fetuses. Rather than using severe variable decelerations or bradycardia to trigger amnioinfusion, Sarno's "fetal admission test" may identify early in labor those in whom ominous patterns are likely to develop at a time when amnioinfusion can be done under more controlled, relaxed conditions. Therefore, we propose that detection and correction of oligohydramnios early in labor has more utility than a protocol that waits for the appearance of ominous patterns before reacting. With the knowledge that 250 ml of normal saline solution will increase the amniotic fluid index by roughly 4 cm, the practitioner can use amnioinfusion more effectively by titrating the infusion to an appropriate amniotic fluid index.

Cordocentesis and immune thrombocytopenia—Continued

To the Editors: I thank Dr. Daffos for his response[1] to my letter of inquiry[2] requesting references to support his conclusion that fetal blood sampling should be used in the evaluation of pregnancies complicated by autoimmune thrombocytopenia. My specific request was stimulated by his statement that "The occurrence of fetal bleeding accidents during pregnancy is more frequent in this condition (i.e., autoimmune thrombocytopenia) than in cases of alloimmunization, so it is important to know the fetal platelet count as early as possible to attempt to treat the fetus via maternal therapy." In response to my query, Dr. Daffos offered seven references to support this statement. I have reviewed each and find them lacking.

The first reference was a commentary in the *British Journal of Obstetrics and Gynaecology* concerning both autoimmune thrombocytopenia and alloimmune thrombocytopenia.[4] No where in the Discussion section do the authors suggest or report evidence of *fetal* hemorrhage as a result of autoimmune thrombocytopenia. They do reference several publications (some of which Dr. Daffos included). None of these publications documents a single instance of a *fetal* hemorrhage from autoimmune thrombocytopenia. All the untoward complications of autoimmune thrombocytopenia occurred in the neonatal period.

The second reference also appeared in the *British Journal of Obstetrics and Gynaecology*.[5] It reviews 51 pregnancies complicated by autoimmune thrombocytopenia. It includes six neonates delivered vaginally whose platelet counts were <50,000. As summarized on page 681 of that article, all bleeding complications occurred in the neonatal period.

The third reference offered[6] was a review article in *Annals of Internal Medicine*. Dr. Kelton effectively argues the opposite of Dr. Daffos that the outcome of pregnancies complicated by autoimmune thrombocytopenia is not as bad in prospective studies as suggested by isolated case reports. He cites his unpublished study in which only 10 of 94 live-born infants had a hemostatic defect and all bleeding complications occurred in the *neonatal period.* In a prior report on autoimmune thrombocytopenia (AM J OBSTET GYNECOL 1982;144:449), Dr. Kelton reported on 41 pregnancies in which there were five stillbirths or late abortions. Two women had lupus, two had preeclampsia, and the fifth had negative test results for platelet associated immunoglobulin G.

The fourth reference was cited erroneously.[7] The correct page number follows this letter. Drs. Hind et al. report a single case of autoimmune thrombocytopenia treated at 36 weeks' gestation with gammaglobulin. There were no fetal or neonatal bleeding complications. The authors then reviewed 18 reports of 159 deliveries published between 1973 and 1982. There were no instances of antenatal hemorrhage. All perinatal bleeding complications occurred in the neonatal period. Perinatal mortality was not broken into the fetal and neonatal periods. However, the perinatal loss rate and neonatal intracranial hemorrhage rate happen to be the same (2.4%).

The fifth reference[8] appeared in the *British Medical Journal.* This is a case report of a single fetus; the mother was treated with immune globulin before delivery. The neonatal platelet count was normal after spontaneous vaginal delivery.

The sixth reference[9] appeared in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY. These authors studied alloimmune thrombocytopenia and therefore it is not relevant for the assignment of risk from autoimmune thrombocytopenia.

The final reference that Dr. Daffos supplied appeared in *Obstetrics and Gynecology*.[10] This report reviews five cases. In case one the bleeding complications were limited to the neonatal period. In case two the history is more consistent with alloimmune thrombocytopenia inasmuch as maternal thrombocytopenia could never be documented. In case three the woman had a severe preeclampsia associated with thrombocytopenia and the fetus had a normal platelet count. In case four there was an intrauterine fetal death at 28 weeks' gestation when the patient's platelet count was normal. No evidence of fetal hemorrhage during the intrapartum period was apparently found. In case five there were no bleeding complications.

I do not suggest that it poses absolutely no risk to the fetus. I accept antenatal hemorrhage has probably occurred. However, it is hard to believe that if autoimmune thrombocytopenia posed a sizable *fetal* risk, antenatal hemorrhage would not already have been documented in the literature considering its frequency of occurrence. A rare loss should be expected because a sizable percentage of women with autoimmune thrombocytopenia have other disorders such as lupus. This disorder must be separated from alloimmune thrombocytopenia where the fetal risk is sizable.

In summary, none of the references provided by Dr. Daffos offers any support for his statement that autoimmune thrombocytopenia poses a significant risk to the fetus. To recommend cordocentesis without documentation as to what the risk of disease to the fetus is perpetuates a modern myth. Cordocentesis poses a small but finite fetal risk even in the best hands and complications of procedures performed for this indication have been reported.[11] We will all agree that during the neonatal period, autoimmune thrombocytopenia does pose a risk. However, most of the neonatal complications can be prevented by modern practices. There is no justification to place the fetus at greater risk by performing an unindicated, invasive procedure.

Maternal serum unconjugated estriol levels are lower in the presence of fetal Down syndrome

To the Editors: The recent article by Macri and his colleagues (Macri JN, Kasturi RV, Krantz DA, Cook EJ, Sunderji SG, Larsen JW. Maternal serum Down syndrome screening: unconjugated estriol is not useful. Am J Obstet Gynecol 1990;162:672-3) has prompted us to summarize all the published data sets that have come to our attention that examine the relation between unconjugated maternal serum estriol levels in the second trimester and fetal Down syndrome (affected pregnancies). Table I lists the study site, number of affected pregnancies, and median unconjugated estriol multiples of the median in affected pregnancies. An additional data set that includes 54 affected pregnancies with a median unconjugated estriol of 0.71 multiples of the median has come to our attention (MacDonald M, Wagner R. Genetrix, Scottsdale, Ariz.

Table I. Median maternal serum unconjugated estriol levels in pregnancies with fetal Down syndrome in the second trimester

Site and reference	*No. of affected pregnancies*	*Unconjugated estriol multiples of the median in affected pregnancies*
Michigan[1]	26	0.52
Massachusetts[2]	26	0.62*
Texas[3]	22	0.70
Oxford, England[4]	77	0.73
Denmark[5]	42	0.74
Rhode Island/Maine[6]	22	0.79
New York[7]	41	1.00*
Total	256	0.75†

*Ratio of unconjugated estriol in affected to unaffected pregnancies.

†Weighted for the number of affected pregnancies.

Personal communication) but is not included in Table I because it is not yet published.

As a group, the studies yield a median unconjugated estriol of 0.74 multiples of the median for affected pregnancies, with a range of 0.52 to 0.99. This range of values is similar to the range of values reported for α-fetoprotein by various centers,[8] after its discovery as being associated with Down syndrome in 1984. With α-fetoprotein, the assembled data also contained one value from a study that failed to find an association. Ultimately the group consensus was found to be correct, and this is likely to be the case with unconjugated estriol as well.

Reply

To the Editors: Dr. Haddow et al. call attention to the fact that our published research findings[1] on unconjugated estriol differ from the findings of others.[2-3] It is precisely this fact that prompted our publication. On the basis of a number of studies, the theoretic basis used by Haddow et al. and their research findings deserve close scrutiny before implementation. In a review of references cited by the authors of the letter we find, in fact, support for our caution about the ineffectiveness of unconjugated estriol:

The results suggest that while βhCG levels are independent of the DS ascertainment method, UE levels are low in the [low] AFP group and normal in the [normal] NAFP group. Thus, UE and AFP may not be independent markers in DS pregnancies.

Fisher et al.[4]

This analysis largely confirms the previous statistical analysis of Wald et al.; however, the relative benefit of using unconjugated estriol levels should be studied in greater detail.

Del Junco et al.[5]

The screening performance based on these two markers [MSAFP and hCG] and age does not seem much inferior to that obtainable by including estriol also.

Norgaard-Pedersen et al.[6]

Additional publications on maternal serum unconjugated estriol in Down syndrome screening reveal the following:

If only two of the three biochemical tests are to be used alpha-fetoprotein and human chorionic gonadotropin concentrations is the pair of choice, as alpha-fetoprotein concentration is of separate value in screening for neural tube defects and the performance of alpha-fetoprotein and human chorionic gonadotropin concentrations in combination is not much worse than that of unconjugated oestriol and human chorionic gonadotropin concentrations in combination.

Wald et al.[7]

Our assay results show the SD [standard deviation] of the MSE MoM for the unaffected population to be greater than reported. This means greater overlap of the Down's and unaffected populations and less effectiveness as a screening test.

Swanson[8]

Our model, without the additional measurement of unconjugated estriol levels, appears to be comparable in sensitivity to the analysis proposed by Wald et al.

Petrocik et al.[9]

Canick[10] postulated that, because maternal serum α-fetoprotein was lower in cases of Down syndrome (because of lowered fetal liver production), other markers of fetoplacental origin, specifically unconjugated estriol, should also be lowered. However, Seller[11] has shown that before 20 weeks' gestation the production of α-fetoprotein is not lower in cases of Down syndrome than that in chromosomally normal fetuses. This observation challenges the theoretic basis of the findings of Canick.

In another study[12] from this laboratory, the data show that with the use of certain assays that measure maternal serum unconjugated estriol, marginally higher levels are found in Down syndrome cases compared with controls. Hence unconjugated estriol may not only fail to contribute to detection efficiency of this syndrome, but actually reduce the overall effectiveness of Down syndrome screening. In view of such findings great caution should be exercised before implementation.

Rather than caution, rapid commercialization of a Down syndrome screening protocol including unconjugated estriol is in progress. This is apparent from commercial advertisements that have appeared regularly in the clinical obstetric and genetic literature offering the routine use of unconjugated estriol. During this early developmental stage in Down syndrome screening it is inappropriate to subject clinicians and

patients to the uncertainty about the effectiveness of unconjugated estriol that exists in the biomedical research community. If the very investigators who find low levels of unconjugated estriol are equivocal and skeptical of its use as a marker in Down syndrome screening, patients and physicians should not be pressed to premature human investigation, much less to routine clinical use.

Measures of test performance and predictive values

To the Editors:

So all my best is dressing old words new.
Shakespeare
Sonnet 76

In their recent article dealing with the prediction of residual trophoblastic tissue after first-trimester abortion, Schiff et al. (Schiff E, Ben-Baruch G, Moran I, et al. Prediction of residual trophoblastic tissue in first-trimester abortion and low levels of human chorionic gonadotropin β-subunit. Am J Obstet Gynecol 1990;162:797-801) commented on page 800 that "this test has a sensitivity of 86.4%, and a false-negative rate of 3.2% but a specificity of 60.5% and a false-positive rate of 75.9%." It is an elementary fact that the false-negative rate and the true-positive rate (or sensitivity) of a test add up to one (or 100%, depending on whether these rates, which are infact fractions, not true "rates," are expressed as proportions or percentages); the same applies to the false-positive rate and the true-negative rate (or specificity) of a test. Therefore it is self-evident that the above figures cannot be correct.

As if to underscore the need to keep separate in one's mind measures of test performance (true-positive rate, false-negative rate, true-negative rate, and false-positive rate) and predictive values, which I suggested in a previous letter could best be done by thinking of these fractions in terms of conditional probability,[1] these authors have confused their test's false-negative predictive value with the false-negative rate and the test's false-positive predictive value with the false-positive rate. In fact, the false positive rate of their test was 39.5% (60/152); since the sensitivity was 86.4%, the likelihood ratio of the test, which is the true positive rate divided by the false-positive rate, is 2.2. This in turn means that the prior odds on disease (disease, in the present context, refering to the presence of residual trophoblastic tissue in the uterus) are roughly doubled if the test is positive (Posterior odds = Prior odds × Likelihood ratio).

The prior odds on disease in the study were 1:7 (22:152); therefore the posterior odds are 2:7, and the posterior probability of disease 2:9, or approximately 22%. (If O stands for odds, and p stands for probability, then $p = O/1 + O$, and $O = p/1 - p$). Thus, even if we were to intervene for a positive test result (i.e., only if the authors' κ-value was above the designated value), the woman in question would still be four times more likely not to have, than to have, residual tissue in the uterus. Or, to put the matter the other way around, the authors have tried to persuade us that we would intervene unnecessarily less often if we used their test than if we did not. In fact, the opposite is true, given that with a prevalence of residual tissue of only 12.6% no one would adopt a policy of routine curettage for such patients.

That is not to say that the authors' test provides no

diagnostic information, even if that information is of questionable practical value. If the consequences of delaying a necessary curettage were sufficiently detrimental as to warrant curettage in all women (and there is no evidence that it is), then the authors' test would enable one to reduce the number of unnecessary curettages needed to avoid delaying one necessary curettage from 7 to 3 (with delay nonetheless occurring in approximately 14% of cases requiring curettage). This all presupposes, of course, that the authors' method is valid, which it is not, because it is an example of what might be called statistical tautology. They have defined the test using data from 174 patients and then proceeded to test the efficacy of that test on the same 174 patients. Regression toward the mean will always ensure that a given data set will maximize the performance of a test defined on that data set. *Per contra,* the utility of the test when applied to future data sets will always be less. (This is the statistical basis underlying what I believe used to be called the "gee-whiz" phenomenon). One therefore needs no prospective randomized study to deduce that the authors' method will not perform as well in future data sets as it did in the original sample of patients.

To the Editors:

Why with the time do I not glance aside to new-found methods and to compounds strange?
Shakespeare
Sonnet 76

We read with interest Dr. Kadar's comments on our article. It seems that there is disagreement regarding the way of calculating the false-positive rate and the false-negative rate. This difference of opinion is also expressed in the letters of Dr. Kadar and Dr. Kolins published in the JOURNAL.[1,2] We prefer to use Dr. Kolins' method by which the false-positive rate is calculated as the percentage of all positive results that were false-positive. In this way the false-positive rate complements the positive predictive value and not the specificity to 1. It seems to us that in this way the disadvantage of the test is more clearly presented. However, since we are dealing with definitions only, which do not change the character of the results, it would be even simpler to represent the false-positive rate in our study as 39.5% instead of 75.9% and this last value as 1 − Positive predictive value.

The statement that curettage is not performed routinely in women such as those described in our study is incorrect. Many physicians are not aware that residual trophoblastic tissue is identified in the curettings in only 13% of these cases. In many centers, as we know, even if one is aware of this fact, it is preferred to perform a curettage, or at least the question arises as to which women should undergo curettage. This is exactly the clinical question we attempted to answer. Therefore, even if the posterior odds ratio is 2:7 and the likelihood ratio of the test is 2.2, a significant percentage (60%) of the curettages could have been prevented. This does not conflict with the fact, also pointed out by us, that there is still a high proportion among the remaining 40% of curettages performed that were unnecessary.

Toxicity of vancomycin given during pregnancy

To the Editors: In a recent issue of the JOURNAL Reyes et al. (Reyes MP, Ostrea EM, Cabinian AE, Schmitt C, Rintelmann W. Vancomycin during pregnancy: Does it cause hearing loss or nephrotoxicity in the infant? AM J OBSTET GYNECOL 1989;161:977-81) concluded that vancomycin administration during pregnancy does not produce nephrotoxicity in the newborn infant since plasma creatinine levels were within normal limits at birth. Noteworthy is the fact that it is usually admitted that maternal and fetal plasma creatinine levels are physiologically equilibrated at birth.[1,2] For instance, the comparison of plasma creatinine levels (mean ± SEM) obtained at the time of birth in 16 neonates (7.75 ± 0.83 mg/L) and their mothers (6.67 ± 0.80 mg/L) disclosed a strongly significant relationship ($r = 0.969$; $p < 0.001$) (unpublished data). Subsequently, plasma creatinine levels progressively decline from birth to the fifth day of life in term neonates and to the twenty-first day of life in preterm infants.[1-3] Thus plasma creatinine level at birth is not a reliable marker of glomerular filtration rate,[3] and the study of Reyes et al. does not allow any conclusion to be drawn on vancomycin's nephrotoxicity in newborn infants. Further studies using creatinine or inulin clearances are needed.

Reply

To the Editors: We agree with Drs. Gouyon and Petion that plasma creatinine levels of the infant at birth are affected by placental clearance and may be normal. In our study serum creatinine levels were obtained 4 to 6 days after birth in seven of 10 infants born to drug-dependent mothers who received vancomycin during pregnancy. We believe that some elevation of the serum creatinine level would have been evident in these infants at the time of blood sampling if significant renal dysfunction occurred in utero.

Ethics of new reproductive technologies

To the Editors: The recent discussion of ethics and reproduction by Professor Macnaughton (Mcnaughton M. Ethics and reproduction. AM J OBSTET GYNECOL 1990;162:879-82) deserves additional comment. His opening paragraph discusses our objective as physicians as one of doing good and not harm, and I believe that this is an admirable goal. However, the bulk of his remaining discussion ignores the irreparable harm inflicted on patients from the various reproductive technologies.

Specifically his compilation of deaths as a result of pregnancy-related complications and illegal abortions is not compared to the millions of deaths of human fetuses by sanctioned abortions. Nor does it address the psychological harm suffered by the person undergoing the abortion.

The ethical opinion expressed regarding human embryo research adroitly skirts the issue of life but rather dwells on a concept of personhood to justify this harm. What respect is shown to this life if it is not allowed to complete its potential?

Advances in reproductive technologies that maintain respect for human life should be pursued and applied to the care of our patients. Those that prevent this life from reaching its potential are unworthy of our profession.

Robert J. Blaskiewicz, MD
2821 North Ballas Road, St. Louis, MO 63131

Reply

To the Editors: Professor Blaskiewicz in his letter puts forward the usual arguments of the so-called pro-life lobby. I am not clear how he comes to the conclusion that the new reproductive technologies have inflicted irreparable harm on patients. I can only conclude that he has not been involved himself and really knows nothing about this because my own experience is exactly the opposite.

His arguments against abortion are the usual ones. He seems to be able to tolerate 20% of maternal deaths in the world being due to illegal abortion when we know legal abortion would greatly reduce all this suffering. I consider that quite unacceptable from an ethical point of view. He, of course, must equate the value of a fetus or an embryo above that of the mother and again I cannot agree.

Questions of the origin of life are philsophical and moral ones. Professor Blaskiewicz seems to consider the early embryo to deserve the same respect as a child or an adult. He is entitled to that view, of course, but I do not share it and neither does the British Parliament, which recently voted overwhemlmingly for embryo research to continue under strict control. He also seems to consider that potential life deserves the same respect as actual life. That is similar to saying that because the Prince of Wales is a potential king he must be treated as a king. Patently not true.

I take exception to the implication that those of us involved in new reproductive techniques and in the prevention of maternal death are less caring than the so-called pro-life lobby and I am sure the majority of women have the same view.

Twin transfusion syndrome

To the Editors: Shah and Chaffin are absolutely correct to point out the complexities of the diagnosis and management of twin-to-twin transfusion syndrome (Shah DM, Chaffin D. Perinatal outcome in very preterm births with twin-twin transfusion syndrome. AM J OBSTET GYNECOL 1989;161:1111-3). However, I would respectfully suggest that simply an asynchronous hematocrit or birth weight is insufficient evidence on which to base a diagnosis of twin transfusion syndrome, even with monochorial placentation.

I have a special interest in twin transfusion syndrome and would offer the following comments on the basis of my experience. The authors do not discuss how the monochorionicity was confirmed or whether there were injection studies of the fetal circulations of the placentas. This is important because not all monochorial placentas have vascular anastomoses, and without such anastomoses a diagnosis of twin transfusion syndrome seems tenuous. Also, not all discordant growth in monochorial twins is due to twin transfusion. I have seen intertwin discordance of weights of as much as 25%, or even more, which is attributable to asymmetric development of the chorion or asymmetric placental abnormality such as villitis. In addition, the recipient of a twin transfusion may be edematous and be heavier than the co-twin for that reason as well. Thus I have found that linear measurements of infants are often of additional help when comparing intrauterine growth of twins. Similarly, differential hemoglobin values

need to be correlated with the presence and pattern of fetal vascular anastomosis, as well as any evidence of fetal-maternal hemorrhage. Significant fetal-maternal hemorrhage may occur coincidentally with twin transfusion and lead to a significant unilateral anemia of twins. Finally, the authors would do well to differentiate chronic from acute twin transfusion, because the associated pathologic conditions and clinical consequences are different, as are the diagnostic criteria. The chronic twin transfusion syndrome may have helpful ultrasonographic manifestations, although the above additional possibilities must be kept in mind, while acute twin transfusion will not likely be manifested until birth.

Very preterm twins do poorly generally and have an even worse prognosis when truly involved in a twin transfusion. Any intragestational intervention requires accurate diagnosis and can be undertaken only with an awareness of the fact that there is occasional spontaneous subsidence, or even reversal, of twin transfusion. In addition, the source of the disorder is also the source of potential problems with intrauterine therapy, and adequate appreciation of the (as yet) unknowable extent of this potential is required before intervention is undertaken.[1] As Shah and Chaffin pointed out, correlation of the clinical state of the infants must be made with complete details of placental morphologic characteristics before useful interpretations as to the pathophysiologic features can be suggested. In fact, it may take the combined efforts of the placentologist–perinatal pathologist, obstetrician-perinatologist, ultrasonographer–Doppler study expert to sort out the events associated with intertwin vascular anastomosis. It can be a daunting prospect but one that is worthy of detailed assessment considering the seriousness of the condition and suggested interventions.

Reply

To the Editors: We appreciate Dr. Baldwin's interest in our article. The diagnosis of twin-twin transfusion in our series was based on retrospective review of the clinical spectrum, laboratory values, and pathologic examination of the placenta. Although clinical evaluation by neonatologists lends significant credence to such a diagnosis, it is not a measurable parameter. In addition, the literature provides definable criteria for diagnosis, as used in our report. Vascular injection studies were not performed consistently enough to be used for the purpose of study. We accept Dr. Baldwin's criticism about diagnostic criteria but respectfully submit that we are very comfortable with the twin-twin transfusion diagnosis in our series, since it was arrived at after extensive critical review of each case while blinding ourselves to the outcome.

We are not sure what Dr. Baldwin means by asymmetric development of chorion. We would suggest that such a pathologic finding may be a consequence or end result of a chronic in utero twin-twin transfusion. Her suggestion about linear measurements is interesting; however, our experience suggests that linear somatic growth deficiency does occur as a result of severe chronic twin-twin transfusion. All the cases reported in the series, in our opinion, are the result of chronic in utero twin-twin transfusion leading to very preterm delivery. We agree with Dr. Baldwin that acute peripartal twin transfusion does occur and is a consequence of or associated with delivery, but it is not the cause of very preterm delivery as suggested in our series.

We appreciate Dr. Baldwin's support of our contention that consideration of intragestation intervention requires accurate diagnosis. Our experience suggests that spontaneous subsidence or reversal of the twin transfusion process recognized before 28 weeks' gestation must be an extraordinarily rare event. We agree with her that complex problems may be faced in therapeutic attempts. We thank her for supporting what is also our contention: that multifaceted analysis and prenatal evaluation are necessary to understand the pathophysiologic characteristics and that it is a worthy prospect considering the grave consequences of the disorder as supported by our review.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

آغا خان یونیورسٹی

THE AGA KHAN UNIVERSITY

Faculty of Health Sciences
Medical College

The Aga Khan University is now in its seventh year of operation. Its affiliated Aga Khan University Hospital has well equipped teaching and service laboratories and will have 654 beds when fully operational. The University and the University Hospital are autonomous, privately funded and philanthropic institutions committed to the provision of effective health professional education and health services relevant to Pakistan and the region. Our undergraduate curriculum in medicine stresses integrated training of the basic and clinical sciences with a hands on, problem solving approach to patient care and parallel extensive training in Community Health Sciences.

The Department of Obstetrics and Gynaecology was commissioned in January 1987 and at present there are 6 full-time faculty members working in the Department. The out-patient clinics are heavily scheduled and we are presently doing about 140 deliveries every month. Patient volume and clinical work load are gradually increasing and it is envisaged that there will be 85 Obstetrics and Gynaecology beds at full operation.

We are currently seeking candidates for the following positions:

ASSISTANT PROFESSOR, OBSTETRICS AND GYNAECOLOGY

Candidates applying for this position are required to have completed their postgraduate training in the related field with speciality certification, and must have 3 to 4 years of subsequent clinical and teaching experience.

INSTRUCTOR, OBSTETRICS AND GYNAECOLOGY

Candidates applying for this position are expected to have completed their postgraduate training in Obstetrics and Gynaecology with speciality certification (F.C.P.S. MRCOG, American Boards or equivalent).

Salary and benefits will be offered commensurate with qualifications, experience and level of responsibility. Candidates intending to pursue a career in Pakistan will be preferred. Applications should include detailed résumé, bibliography and names of at least three referees familiar with recent work history. Reply to the **Personnel Director**, The Aga Khan University, P.O. Box 3500, Stadium Road, Karachi-74800, Pakistan.

• Gynecologic Oncologist • Reproductive Endocrinologist
• Clinical Geneticist

The Baystate Medical Center is the major provider of tertiary care in Western Massachusetts. It has recently expanded its resources through its designation as the Western Campus for Tufts University Medical School. In response, the Department of Obstetrics and Gynecology is expanding its full time faculty group.

The Department has over six thousand deliveries and three thousand operative procedures. Our staff consists of forty-five community based physicians, five certified nurse midwives, and eleven full time faculty in the fields of Maternal-Fetal Medicine, Reproductive Endocrinology, Gynecologic Oncology and Primary Care. The Department has a major commitment to Student Education and has an independent Resident Education Program with twenty residents. Excellent opportunities exist for basic and clinical investigation in many areas.

Baystate Medical Center offers a salary and academic rank commensurate with experience. The Department also has a practice plan. Send Curriculum Vitae or contact:

Laurence E. Lundy, MD, Chairman, Obstetrics and Gynecology
John Powell, MD, Chief, Gynecologic Oncology
Patrick O'Grady, MD, Chief, Maternal Fetal Medicine
Halina Wiczyk, MD, Chief, Reproductive Endocrinology

CHAIR–OB/GYN

830–bed regional tertiary care, teaching hospital is seeking a Chair for its Department of OB/GYN. The Allentown Hospital–Lehigh Valley Hospital Center has 33 active OB/GYN staff physicians, including a gynecologic oncologist and a reproductive endocrinologist. The current Chair of the Department, who will be leaving at the end of this year, is a perinatologist. The hospital has a fully–approved free–standing OB/GYN Residency Program with two residents each year; it will be making application for a third resident in 1991. The department is also in the process of filling a newly–created position of Program Director of the OB/GYN Residency Program. The hospital trains a total of 70 residents and 400 medical students each year.

The hospital is a regional Level III Perinatal Center. Of over 3,000 births in 1989, 42% were in the high–risk category. The department is supported by a 20–bed Level III NICU and has an active OB/GYN clinic which experienced over 8,000 visits in 1989.

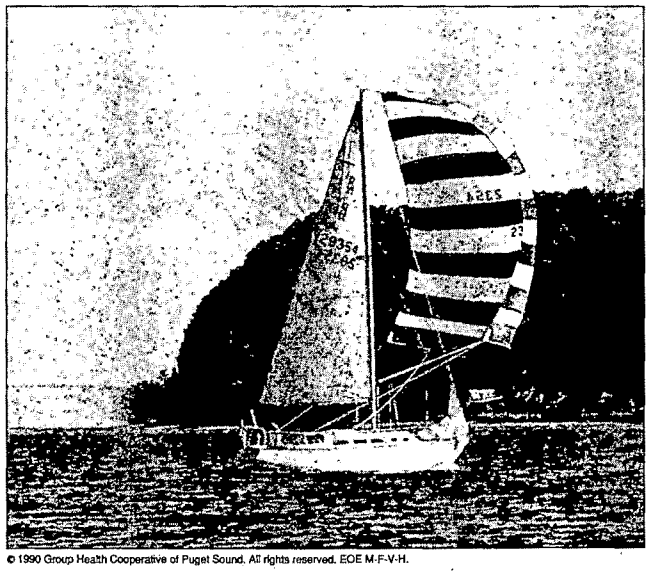
The hospital is a component of HealthEast, a regional, not–for–profit health care system, and is a clinical campus of Hahnemann University in Philadelphia, where the new Chair will hold a vice–chair appointment and an academic appointment at the rank of associate or full professor. The hospital is located in Allentown, a growing metropolitan area in Eastern Pennsylvania, in close proximity to both Philadelphia and New York City.

Candidates must be board–certified physicians with administrative experience and familiarity with both academic and community hospital environments. Interested candidates may write or call for information and send a curriculum vitae, in confidence, to **Headley S. White, Jr., M.D., Sr. Vice President, Medical and Academic Affairs, c/o HealthSearch, 50 College Drive, Suite 323, Allentown, PA 18104, (215) 778–7993.** A descriptive brochure is available.

OBSTETRICAN/GYNECOLOGIST COLUMBIA, SOUTH CAROLINA

A progressive six man OB/GYN Practice with a Maternal-Fetal Medicine Specialist is seeking an additional partner to practice obstetrics and gynecology.

This practice is based at one hospital, has a new office, two ultrasound machines, and in-office laser surgery. We are very active in high risk pregnancies and operative laparoscopy.



We are looking for a board certified or board eligible, young physician to associate with this practice on a permanent basis. Salary is competitive with comprehensive fringe benefits package.

Association will lead to full and equal partnership. We are seeking a new partner as of July 1, 1991.

For more information, please send a letter and Curriculum Vitae to:

THE DEPARTMENT OF OBSTETRICS AND GYNECOLOGY UNIVERSITY OF WISCONSIN MEDICAL SCHOOL MILWAUKEE CLINICAL CAMPUS

is seeking applicants for four (4) full-time faculty positions to participate in the development of a new women's health center and academic program.

Sinai Samaritan Medical Center is in the process of consolidating its obstetrical and gynecological services in a redesigned facility in downtown Milwaukee. The department supports a residency program, the largest perinatal service in Wisconsin (5200 deliveries), consultative ultrasound, genetic and infectious disease programs, and reproductive/endocrine services (including an IVF program). The department is affiliated with Planned Parenthood of Wisconsin.

Qualifications include board candidacy or certification in obstetrics and gynecology and a commitment to teaching residents, medical students, and clinical research. Qualifications for the four positions for GENERAL OB/GYN can take into consideration special individual interests. Special expertise of interest for the department are:

- STATEWIDE FAMILY PLANNING AND AMBULATORY CARE (Part time medical director, Planned Parenthood)
- OPERATIVE LAPAROSCOPY, HYSTEROSCOPY
- UROGYNECOLOGY
- RESIDENT/MEDICAL STUDENT EDUCATION
- OB/GYN ULTRASOUND

Private practice opportunities are also available in an associated offsite multispecialty clinic and all faclty members participate in a group practice at the location.

ALBANY MEDICAL COLLEGE

Rapidly expanding division in our Department of Ob/Gyn needs a third board eligible/certified individual. Candidates should have a strong background in obstetric ultrasound as well as a commitment for medical student and resident education. Protected time for research and other academic pursuits guaranteed. New facility nearing completion. Academic rank in accordance with experience. Competitive salary plus attractive faculty incentive plan provided.

Albany, capital of New York State, offers major cultural and recreational opportunities as well as a variety of life styles in a sane environment.

INTERESTED CANDIDATES SHOULD SEND A LETTER OF INTEREST WITH CV TO:

Myron Gordon, M.D.
Chairman, Department of OB/GYN
Albany Medical College A-74
47 New Scotland Avenue
Albany, New York 12208
OR
Paul J. Weinbaum, M.D.
Head, Division of Maternal-Fetal Medicine
Department of OB/GYN A-133

This is a rapidly growing, two-physician OB/GYN practice offering an excellent full- or part-time position for a BC/BE physician. We're located in beautiful Southeastern New Hampshire, where you'll discover the ideal lifestyle. The location offers proximity to mountains, lakes and seacoast, plus a wealth of cultural attractions. It all adds up to a very healthy family environment.

We're offering a competitive salary, and occurrence malpractice premiums are fully paid. What's more, there's an ownership opportunity after the initial employment period. The position will be available by July, 1991, or earlier.

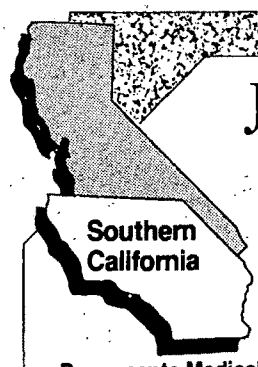
This position has a lot to offer. In a state that has everything.

The group is affiliated with a 330-bed hospital with a Level II Nursery in one of scenic New England's fastest-growing areas, just one hour from Boston.

Reply with CV to: Office Manager, 88 McGregor St., Suite 301, Manchester, NH 03102. (603) 624-8491. This could be everything you always wanted.

COLORADO

BC/BE female/male DO/MD sought to join progressive 2 man group. Association leading to early partnership with excellent income potential. Office located in one of Denver's fastest growing north west suburbs. Opportunity is available July 91 or sooner. Send inquiries and C.V. to:



OFFICE OF MEDICAL AFFAIRS Att: A. E. Murray
LUTHERAN MEDICAL CENTER
8300 WEST 38th Avenue
Wheat Ridge, Colorado 80033

Obstetrics/ Gynecology

WISCONSIN: Marshfield Clinic, a multi-specialty group practice with 350 physicians is seeking BE/BC obstetricians/gynecologists to join expanding (40-50 physician) regional centers in Chippewa Falls and Woodruff, Wisconsin. A third OB/GYN is needed for each facility. Chippewa Falls is located 1 1/2 hours from downtown Minneapolis/St. Paul and twenty minutes from a major four year campus of the University of W sconsin. Known as the "Lakeland Area" (over 1,000 navigable lakes) Woodruff is truly one of the most attractive vacation areas in the upper Midwest and renown for its year-round outdoor recreational activities. Both communities offer exceptional recreational, cultural, and educational opportunities. An emphasis on quality practice and life-style is combined with a total compensation package on reaching membership in excess of $200,000. Starting salary negotiable. Fringe benefit package outstanding; includes self-insured malpractice. No start-up expense. Send C.V. and references to:

David L. Draves
Director, Regional Development
1000 North Oak Avenue
Marshfield, Wisconsin 54449
or call collect at

Marshfield Clinic

Join The Partnership of Choice

With more than 40 years of successful industry leadership, the **Southern California Permanente Medical Group (SCPMG)** is recognized as the nation's largest and most respected physician-managed, multi-specialty medical group. Our continued growth has created new opportunities for:

CHIEF OF SERVICE
Panorama City, CA

An excellent opportunity for an experienced OB/GYN practitioner to lead an established and growing practice at our Panorama City Medical Center. You'll be responsible for supervising 20 OB/GYN Physicians, a Perinatologist, 8 Certified Nurse Midwives and 4 Nurse Practitioners. This team of professionals will handle approximately 3000 deliveries per year.

CHIEF OF SERVICE
Baldwin Park, CA

An exceptional opportunity to build your own team and participate in the development of our newest 240-bed Medical Center. This facility will have a Level IIA Nursery and a 20-bed NICU with a capacity to handle up to 4000 deliveries per year.

Requirements for Chief of Service positions include:

- Board Certified in OB/GYN
- 5+ years practice experience
- Demonstrated leadership abilities
- Strong interpersonal skills

These are ideal opportunities for a physician who wants to combine a busy clinical practice with day-to-day department management responsibilities.

OBSTETRICIANS & GYNECOLOGISTS

You'll have a choice of professional environments ranging from a 250-bed community hospital to a major teaching facility in a number of prime Southern California locations. Our active practices require proficiency in modern ultrasound and surgical techniques.

SCPMG provides the freedom, technology and resources to focus on quality patient care and the collaborative support of knowledgeable colleagues. **We also provide a highly competitive salary, paid malpractice and predictable hours.**

Call or send your CV to:
Irwin P. Goldstein, M.D., Associate Medical Director
SCPMG, Dept. 006
Walnut Center, Pasadena, CA 91188-8013
(800) 541-7946

Contact Christy Carl at (503) 654-7111.

Faculty Position: Assistant Professor, Department Obstetrics, Gynecology and Reproductive Sciences, University of California, San Francisco (UCSF).

The Department of Obstetrics, Gynecology, and Reproductive Sciences, UCSF, announces a national search for an obstetr cian-gynecologist with particular expertise in reproductive genetics to be recruited at the assistant professor level. This is a full-time academic appointment meant to add to the academic, investigative, and teaching program of this reproductive genetics unit and the Department. Applicants should be board certified/eligible in Obstetric and Gynecology and board certified/eligible in Medical Genetics.

Responsibilities will include development of an independent research program in some aspect of reproductive genetics, participation in discharging this unit and department and department's clinical responsibilities, and participation in medical student, house staff, and fellow education. Salary commensurate with experience and academic status.

UCSF is an Equal Opportunity Employer. Women and minorities are encouraged to apply. Please send letters of inquires and curriculum vitae to Mitchell S. Golbus, M.D., Chair, Search Committee, U-262, University of California, San Francisco, San Francisco, CA 94143-0720.

Faculty Position: Chief of Obstetrics and Gynecology, University of San Francisco (UCSF)/Mount Zion Medical Center

The Department of Obstetrics, Gynecology and Reproductive Sciences, UCSF, announces a national search for a chief of the UCSF obstetrics and gynecology service at its Mount Zion Hospital and Medical Center. This is a full-time academic appointment with excellent opportunities to develop a new program which is an integral component of the Department.

The Mount Zion department is developing programs in gynecologic urology, general obstetrics and gynecology, a mature women's (menopausal) program, and gynecologic oncology. The University has established Mount Zion as the site for its new Comprehensive Cancer Center, and the John Kerner Endowed Professorship in Gynecologic Oncology has just been established.

Responsibilities will include medical student and house staff education, junior faculty development, development of a clinical practice, and administration. Research space is available for this individual and/or faculty recruitment. Salary commensurate with experience and academic status.

UCSF is an Equal Opportunity Employer. Women and minorities are encouraged to apply. Please send a curriculum vitae to Mitchell Golbus, M.D., Chair, Search Committee, U-262, University of California, San Francisco, San Francisco, CA 94143.

Fellowship In Reproductive Genetics

The Division of Reproductive Genetics, Department of Obstetrics and Gynecology at The University of Tennessee, Memphis, is offering a two- or three-year fellowship in reproductive genetics beginning July 1991. The fellowship program is approved by the American Board of Medical Genetics. Applicants must have completed a residency in obstetrics and gynecology, and eligibility for medical licensure in Tennessee is required. The fellowship is designed to provide a comprehensive experience in clinical genetics (counseling, prenatal diagnosis, amniocentesis, chorionic villus sampling, fetal blood sampling, ultrasonography, dysmorphology, teratology, alpha-fetoprotein screening). The program emphasizes laboratory training and research in cytogenetics, DNA analyses, inborn errors of metabolism, immunogenetics and population genetics. Fellows are actively involved in clinical and laboratory research projects. Applicants should send a curriculum vitae to: UT Medical Group, Employment Office, 66 N. Pauline, Memphis, TN 38105.

Affirmative Action/Equal Opportunity Employer

ORTHO-NOVUM® 777 Tablets

Smooth Sailing!

norethindrone/ethinyl estradiol

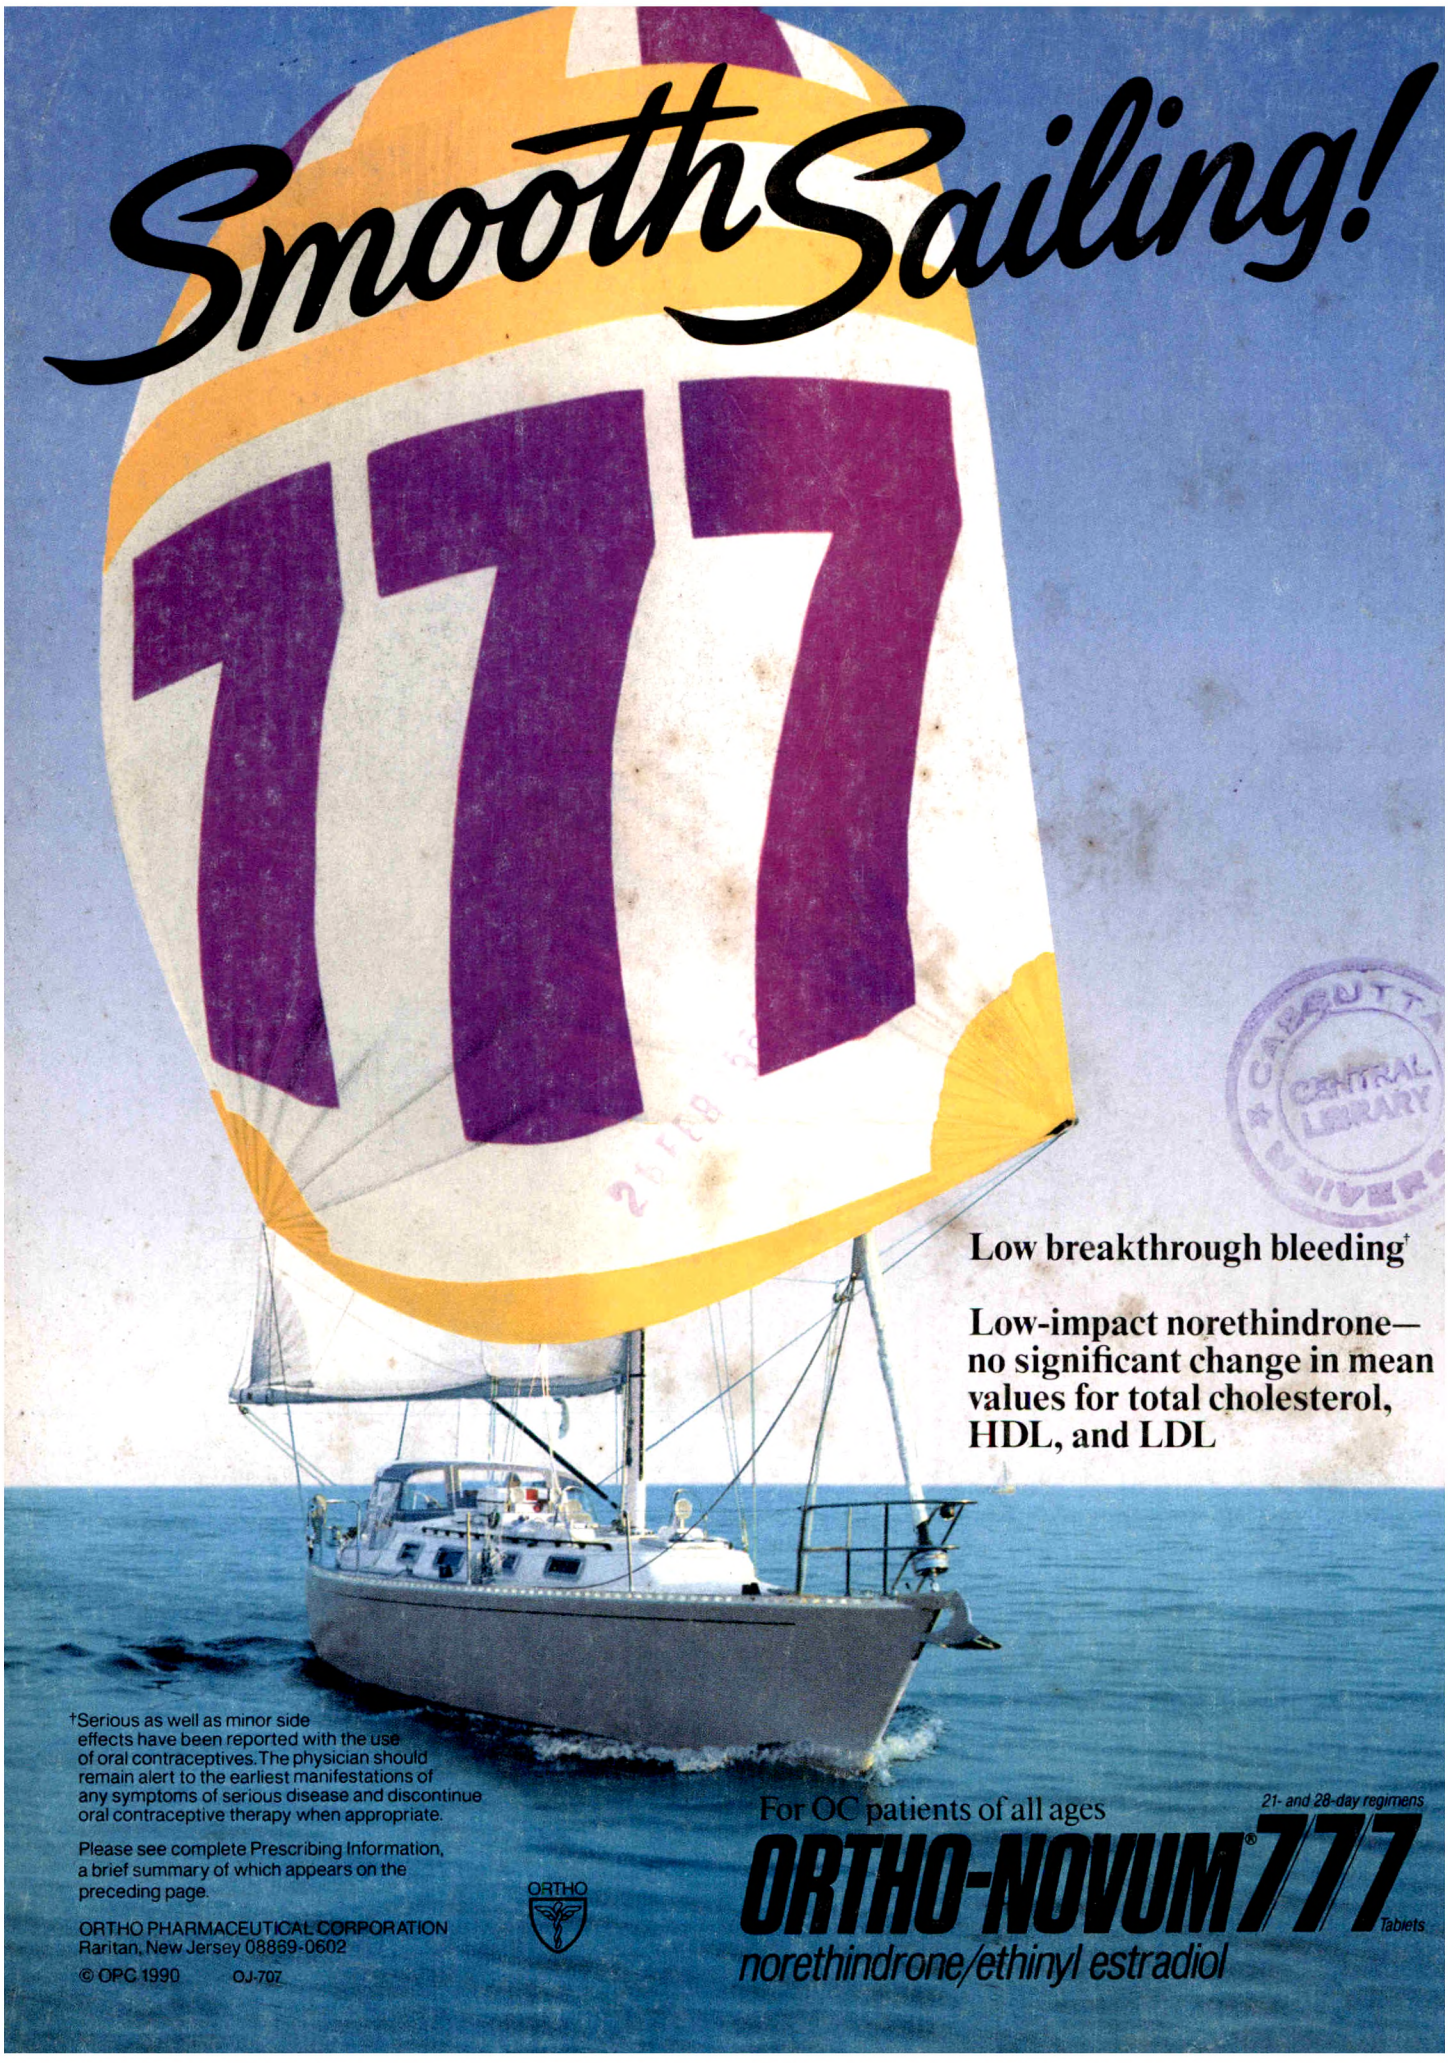
Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28 day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS



Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

PART I: CURRENT CONCERNS IN ORAL CONTRACEPTION

Oral contraceptives and breast cancer 1379
James J. Schlesselman, PhD
Bethesda, Maryland

The lifetime risk of breast cancer does not appear to be appreciably affected by the use of oral contraceptives.

Oral contraceptives, lipoproteins, and atherosclerosis 1388
Michael R. Adams, DVM, Thomas B. Clarkson, DVM, Carol A. Shively, PhD, John S. Parks, PhD, and Jay R. Kaplan, PhD
Winston-Salem, North Carolina

Studies in macaques suggest that lowering of high-density lipoprotein cholesterol by progestins is not atherogenic when a sufficiently potent exogenous estrogen is coadministered.

Oral contraceptives and myocardial infarction 1393
Ian H. Thorneycroft, PhD, MD
New Orleans, Louisiana

Epidemiologic data suggest that the risk of myocardial infarction in oral contraceptive users is limited to women over 35 years who smoke.

PART II: A NEW ERA WITH GESTODENE

Clinical acceptability of monophasic gestodene 1398
Bernd Düsterberg and Klaus Brill
Berlin, West Germany

Results of clinical trials of the monophasic low-dose contraceptive containing 30 μg of ethinyl estradiol and 75 μg of gestodene among 100,000 women are reported.

PART I: CURRENT CONCERNS IN ORAL CONTRACEPTION

Oral contraceptives and breast cancer

James J. Schlesselman, PhD

Bethesda, Maryland

Among women in general the risk of breast cancer through 59 years of age does not appear to be affected appreciably by the use of oral contraceptives. Nonetheless, concern continues to be expressed about the effects of early age at first use, long-term duration of use, formulation, and a variety of other factors thought to influence breast cancer risk in the presence of oral contraception. A number of recent studies restricted to young women suggest that long-term use may increase the risk of disease occurring very early, but the present lack of consistent findings in well-conducted epidemiologic studies prevents any certain conclusion with regard to cause-and-effect. However, if an increased risk were indeed present, the most plausible interpretation is that long-term oral contraception promotes earlier clinical manifestation of breast cancer in some women while having no net impact on their lifetime risk of the disease. (AM J OBSTET GYNECOL 1990;163:1379-87.)

Key words: Breast cancer, oral contraception

More than 60 million women throughout the world now use oral contraceptive agents.[1] The two constituents of oral contraceptives, estrogen and progestogen, are known to play a role in both animal and human carcinogenesis.[2-6] There is considerable disagreement, however, about the effects of oral contraceptives on women's risk of breast cancer. Because hormones are considered to be tumor promoters and not initiators,[4] an adverse effect of oral contraception should be revealed by a dose response with duration of use and should be more readily apparent at younger as opposed to older ages of cancer diagnosis.

The findings of 17 different epidemiologic studies reported since 1980 indicate that the risk of breast cancer through ages 55 to 60 years shows no dose response with total duration of use (Fig. 1).[7-23] *Relative risk* in Fig. 1 refers to the risk of breast cancer in users of oral contraceptives divided by the risk in nonusers. A relative risk of 1.3, for example, denotes a 30% increased risk in users; a relative risk of 0.7, on the other hand, denotes a 30% decreased risk in oral contraceptive users, and a relative risk of 1.0 denotes no association between the risk of breast cancer and use of oral contraceptives. There is also no dose response by duration of use before first-term pregnancy (Fig. 2).[24] The epidemiologic findings are based on use of oral contraceptives predominantly between the ages of 25 and 40 years. An emerging consensus is that oral contraception at these ages has no adverse effect on women's risk of breast cancer through middle age.[25]

A number of recent studies, however, suggest that use of oral contraceptives may increase the risk of very early-occurring disease.[26-30] One strongly advocated hypothesis is that long-term use at young ages is the critical dimension of exposure.[28, 30-32] If this were true, then past studies of older women would not show increased risks of breast cancer: (1) because oral contraceptives were not available to older women for use at young ages and (2) because an effect of oral contraceptives might be restricted entirely to early-occurring breast cancer.

Breast cancer in young women

Fig. 3 shows results from nine studies of breast cancer in women under age 45 years that report estimates of relative risk by total duration of oral contraception.[19, 25-30, 33, 34] The relative risks in Fig. 3 tend to be elevated with use beyond 4 years and are uniformly in excess of 1.0 after 8 years' duration. Figs. 4 and 5

provide study-specific details. The estimates by the United Kingdom National Case-Control Study Group (Fig. 4) reported in May 1989 refer to women under 36 years of age.[30] The study by Pike et al. (Fig. 5) refers to women under 33 years of age.[26]

In 1988 a report from the Royal College of General Practitioners stated that the risk of breast cancer in British women 30 to 34 years of age who had ever used oral contraceptives was significantly increased compared with never users: relative risk = 3.3 (95% con-

fidence interval: 1.3 to 8.8).[22] However, there was no indication of a dose response by duration of use. The risk was also increased in women 25 to 29 years of age who had ever used oral contraceptives, but the estimate (relative risk = 2.5) was very imprecise (95% confidence interval: 0.1 to 52.5) because only six cases of breast cancer were observed in this age range. The risk of breast cancer in women over age 35 years was reported not to be increased for oral contraceptive users. Thus it was suggested that the elevated risk at younger ages for oral contraceptive users might be the result of an accelerated presentation of breast cancer that would otherwise have been diagnosed at a later time.[22]

Fig. 6 shows estimates of the relative risk of breast cancer in women under age 45 years by duration of oral contraceptive use before first-term pregnan-

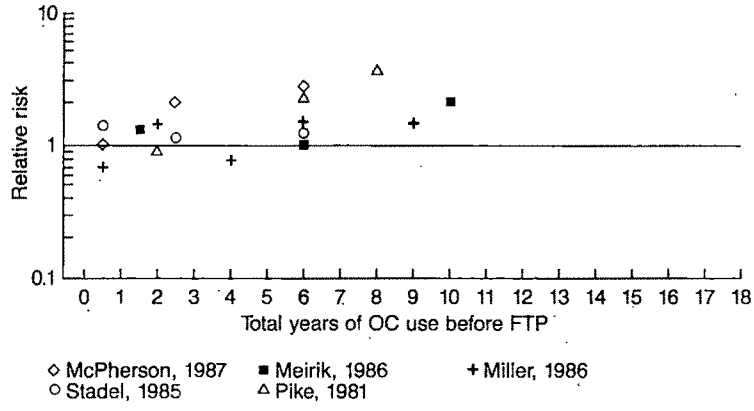

Fig. 8. Breast cancer in women younger than 45 years of age: relative risk by total years of oral contraceptive use before first-term pregnancy. *OC*, Oral contraceptive; *FTP*, first-term pregnancy.

cy.[25-30, 34-36] Because delay of first-term pregnancy itself increases the risk of breast cancer, the relative risks have been adjusted for this factor. The aggregate data suggest a trend of increasing risk with progressively longer periods of oral contraception before first-term pregnancy, with a relative risk of about 1.5 at 4 to 6 years' duration and a relative risk of about 2.0 at 8 to 10 years of use. The evident dose response in Fig. 6 is based on data from nine different studies, only three of which individually show a gradient of risk (United Kingdom, 1989, in Fig. 7; Pike et al., 1981, and McPherson et al., 1987, in Fig. 8).

The Cancer and Steroid Hormone (CASH) Study, which was conducted by the U.S. Centers for Disease Control from 1980 to 1982, shows no effect in young women overall.[35] However, a recent analysis of its data suggests the possibility that prolonged oral contraceptive use in excess of 8 years may accelerate the onset of clinically apparent breast cancer in nulliparous women, particularly those with an early age at menarche.[37, 38] The indication that nulliparous women may be suspectible to an adverse effect of long-term oral contraceptive use is supported by a recent reanalysis of data from the population-based study in Sweden and Norway[39] but not by data from the population-based study in New Zealand (Skegg, DCG. Personal communication, University of Otago, Sept. 6, 1988). The Royal College Study, which also suggests a promotional effect, identifies a different subgroup of women at increased risk—women of parity 1 who use oral contraceptives.[22] The U.K. National Study finds increased risks in both parous and nulliparous women. It also contradicts an earlier study from the United Kingdom in that it reports an effect of oral contraceptive use *after* first-term pregnancy that is just as large as the apparent effect of oral contraceptive use before first-term pregnancy.[30] At present, the absence of any compelling explanation for the striking inconsistencies among these studies prevents any certain conclusion with regard to cause-and-effect.

The rather strong suggestion of an elevated risk of early-occurring breast cancer with long-term oral contraceptive use is not exactly reassuring. One has to be cautious, however, about interpreting studies and find-

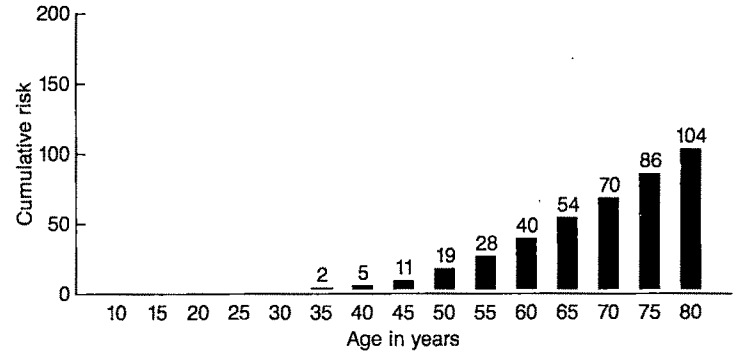

Fig. 9. Breast cancer: cumulative risk per 1000 women, 1981 to 1985, United States.

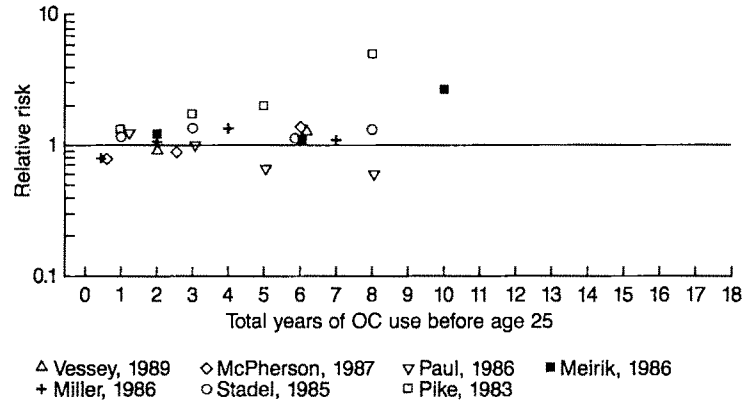

Fig. 10. Breast cancer in women younger than 45 years of age: relative risk by total years of oral contraceptive use before age 25 years.

ings limited to young women, because any alteration in risk found among them may not apply at older ages. Studies of breast cancer in women under age 45 years are restricted to the leading edge of the age-incidence curve. Although the lifetime risk of breast cancer in American women is about 1 in 10,[40] only 1 in 100 (11/1000 in Fig. 9) develops the disease by age 45 years.[41] The recent U.K. National Study was restricted to women under the age of 36 years. The lifetime risk of breast cancer in the United Kingdom is about 1 in 13, but the risk before age 36 years is only about 1 in 500.[42] In the United States the risk of breast cancer before age 36 years is about 1 in 400.[41]

Age at first use, formulation, and latency

Seven studies have presented data on breast cancer risk by duration of oral contraceptive use before 25 years of age.[19, 25, 27, 28, 31, 35, 36] The aggregate data shown in Fig. 10 suggest no dose response, but the findings hint at the possibility that more than 3 years of oral contraceptive use before age 25 years carries a slightly elevated risk of breast cancer. Six of the seven studies report relative risks that exceed 1.0 beyond 3 years of use.

The question whether an early age at first use of oral contraceptives is an important determinant of risk has been addressed in numerous reports. Three population-based studies provide estimates of breast cancer risk by total duration of use in women who started using oral contraceptives before 20 years of age.[19, 30, 35] Fig. 11 shows findings from New Zealand women, 25 to 54 years of age.[19] Fig. 12 shows results in U.S. women, ages 20 to 44 years. Neither study shows evidence of an increased risk of breast cancer in women who started using oral contraceptives at young ages, even in those with long-term use. The U.K. National Study shows a significant dose response by duration of use in women starting oral contraceptives before age 20 years (Fig. 13), but the increased risk is virtually the same regardless of age at first use.[30] Thus duration of use, not age at first use, is the important factor.

Six other studies have reported data on age at first use as a potential breast cancer risk factor.[15, 21, 23, 27, 32, 34] Five of these indicate that age at first use is not important. The one dissenting study[32] was based on interviews that may have been biased.[28, 43]

Effects of oral contraceptive formulation on breast cancer risk have been considered to date in at least 14 different studies reported since 1980.[11-13, 15, 18, 21, 23, 25, 28-31, 34-36, 44, 45] Estimates of risk have

been given on a brand-specific basis, in relation to various classifications of oral contraceptives, and in relation to the type and total dose of estrogen and progestogen. Suggestions of differential effects have appeared in several reports,[28, 30, 31] but none has been decisively confirmed. To give but one example, consider Fig. 14, which shows breast cancer risk in women under age 45 years by type of estrogen (ethinyl estradiol or mestranol) and duration of use. A significant ($p < 0.01$) dose response in breast cancer risk among women

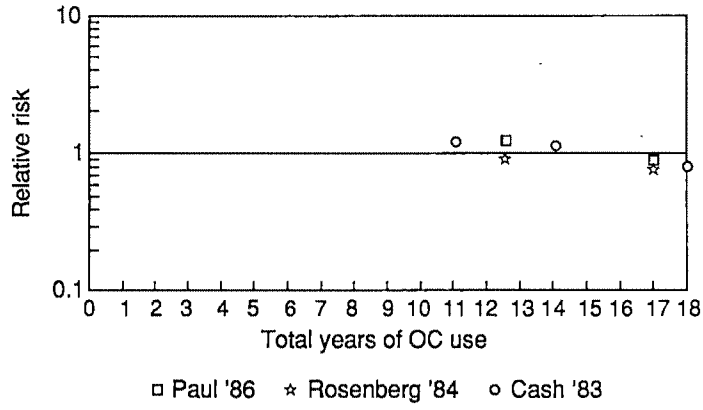

Fig. 15. Breast cancer in women younger than 55 years of age: relative risk by years since first use in women with more than 10 years of oral contraceptive (*OC*) use. (From Schlesselman JJ. Contraception. 1989;40:1-38, Reprinted with permission of Butterworth Publishers.)

using oral contraceptives containing ethinyl estradiol, reported from a study in the United Kingdom, is not supported by data from the CASH Study.

Some investigators have suggested that the "negative" studies can be explained on the basis of a hypothetic long-term latent effect.[46] At least seven reports have addressed this issue directly.[14, 19, 25, 28, 30, 47, 48] None of them, including all the "positive" studies, supports a long-term latency hypothesis.[49, 50] The positive studies only suggest the necessity to accumulate 4 to 8 years of oral contraceptive use before showing an increased risk of early-occurring breast cancer. Fig. 15 shows that in three of the negative studies, no evidence of a latent effect was apparent 10 to 18 years after first use in long-term users.

Studies of oral contraception in women with a family history of breast cancer have reported "positive"[11, 21, 29, 51] and "negative"[13, 14, 17, 20, 52] findings with almost equal frequency. The evidence thus far, which is based on large, well-conducted studies, offers reassurance that women with a family history of breast cancer are not at increased risk of the disease because of oral contraception (Fig. 16). An almost identical situation occurs for benign breast disease, with "positive"[7, 23, 26, 29, 53] and "negative" studies[11, 13, 14, 46] equally divided. Once again, the evidence favors the view that women with *existing* benign breast disease who initiate use of oral contraceptives do not alter their risk of developing breast cancer.[54]

Comment

Results of epidemiologic studies of oral contraceptives and breast cancer are like brush strokes on a canvas. If one stands far enough back from the details, an image seems to appear, whereas careful scrutiny reveals haphazard splashes of color. Such a phenomenon is acceptable in the realm of art, but not in science, where a penetrating gaze should lead to better, not poorer, perception.

The disagreement among even the well-conducted

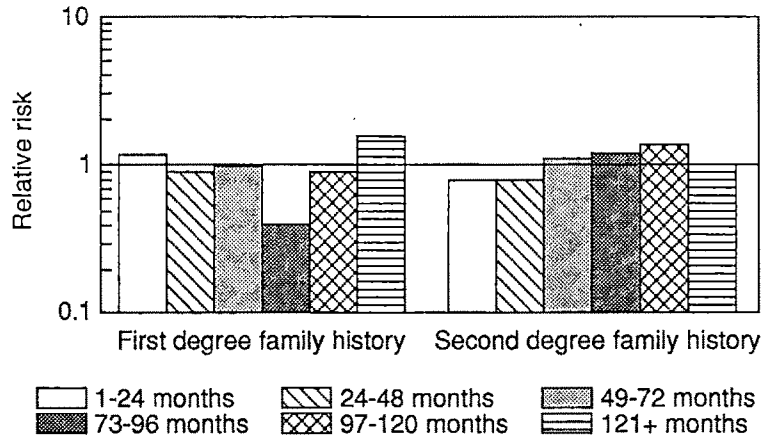

Fig. 16. CASH Study: relative risk of breast cancer in women younger than 55 years of age by total months of oral contraceptive use and family history of breast cancer.

studies suggests that any effect of oral contraceptives on breast cancer risk is likely to be very subtle. This stands in marked contrast to effects of oral contraception on cancers of the endometrium and ovary, in which epidemiologic studies consistently report substantial duration-related protective effects.[24]

Despite the widespread use of oral contraceptives and several reports that suggest increased risks of breast cancer, changes in population-based breast cancer registrations suggest little, if any, effect. In light of the conflicting evidence, regulatory agencies in the United Kingdom and the United States have acted cautiously. In January 1989, an advisory committee to the U.S. Food and Drug Administration recommended no changes in labeling, use, or prescriptions of oral contraceptives. This position was reaffirmed by the Food and Drug Administration later in May 1989 on review of the findings from the U.K. National Case-Control Study.[57] At the same time, the U.K.'s Committee on Safety of Medicines conducted an independent review and, weighing benefits and risks, recommended no change in oral contraceptive prescribing practice on the evidence then available.[58]

I thank Bruce V. Stadel for his comments on the manuscript.

Oral contraceptives, lipoproteins, and atherosclerosis

Michael R. Adams, DVM, Thomas B. Clarkson, DVM, Carol A. Shively, PhD, John S. Parks, PhD, and Jay R. Kaplan, PhD
Winston-Salem, North Carolina

A nonhuman primate model was developed to study the effects of oral contraceptives on lipoproteins and atherosclerosis. Cynomolgus macaques were selected because of their susceptibility to diet-induced atherosclerosis and because their reproductive physiology, menstrual cycle, and circulating sex hormone patterns are similar to those of human females. The first study compared a vaginal ring containing levonorgestrel and estradiol with an oral contraceptive containing norgestrel and ethinyl estradiol. A second study compared two oral combinations: norgestrel–ethinyl estradiol and ethynodiol diacetate–ethinyl estradiol. As predicted, use of all the contraceptives led to lowering of high-density lipoprotein cholesterol levels. However, contrary to what might be expected, use of the ethinyl estradiol–containing oral contraceptives did not lead to an increase in the prevalence or extent of atherosclerosis. We concluded that ethinyl estradiol neutralized the atherogenic influence of the progestin component of oral contraceptives. (Am J Obstet Gynecol 1990;163:1388-93.)

Key words: Coronary artery atherosclerosis, estrogen, high-density lipoprotein cholesterol, oral contraceptive, progestin

It has been established epidemiologically that diminished plasma concentrations of high-density lipoproteins (HDLs) are associated with increased risk of atherosclerosis and coronary heart disease.[1] Because some oral contraceptives are known to lower HDLs, there has been concern that oral contraceptive use will result in increased atherosclerosis and coronary heart disease.[2] Yet it is not clear whether the epidemiologic relationship can be extended to a situation in which plasma lipid profiles have been altered pharmacologically, such as through the use of oral contraceptives. Furthermore, there is no compelling evidence of a widespread adverse influence of oral contraceptives on coronary heart disease. However, because this remains a controversial subject and is one that is difficult to address experimentally in human beings, we have used a nonhuman primate model of atherosclerosis to study the effects of oral contraceptives on lipoproteins and atherosclerosis.

The cynomolgus macaque *(Macaca fascicularis)* has been used in atherosclerosis research for about 25 years, principally because of its susceptibility to diet-induced atherosclerotic involvement of main branch coronary arteries. We chose it for our research because in addition to its susceptibility to diet-induced atherosclerosis, its reproductive physiology is very similar to that of human beings; the female has a 30-day menstrual cycle and circulating sex hormone patterns that are similar to those of women.[3] Also, a natural menopause occurs in aged macaques.

The macaques selected for the experiments were fed an atherogenic diet that is not very different in nutrient composition from that of the average person who is not following current dietary recommendations relative to coronary heart disease prevention. These diets contained about 40% of calories as fat and 0.1% as cholesterol. A feeding period of 2 to 3 years was needed to produce atherosclerotic plaques in coronary arteries. Total plasma cholesterol concentrations averaged 300 to 400 mg/dl. The extent of atherosclerosis was determined at necropsy and involved perfusion fixation of coronary arteries followed by the collection of five serial sections from each of the three major coronary arteries (Fig. 1).

This line of investigation began several years ago with the finding that premenopausal female macaques share with white women in most Western societies a relative sparing of the coronary arteries in atherosclerosis.[4] As shown in Fig. 2, the extent of atherosclerosis in females, as evidenced by lumen stenosis, was about half that observed in males. Also, as in human beings, plasma HDL cholesterol concentration is lower in males than in females and the ratio of total serum cholesterol to HDL cholesterol is higher, but the gender difference in atherosclerosis persists even after statistical adjustment for this lipid difference. Subsequently, we found that ovariectomy resulted in a loss of this gender difference.[5] Physiologic estrogen replacement in ovariectomized macaques was shown to restore this coronary artery protection.[6]

Extent of atherosclerosis, determined morphometrically, is expressed as the average size of the atherosclerotic plaque as *(A)* evident in the histologic section from a coronary artery and *(B)* indicated by the shaded area in the diagram. *EEL*, External elastic lamina, *IEL*, internal elastic lamina.

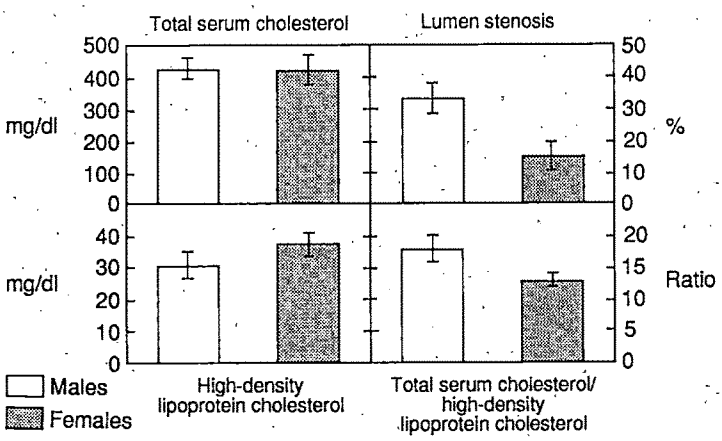

Fig. 2. Serum lipids/lipoprotein profiles and evidence of coronary artery atherosclerosis in male and female cynomolgus macaques. As in human females, macaque females have higher HDL cholesterol and lower total serum cholesterol to HDL cholesterol ratios than do their male counterparts. (Data from Hamm TE Jr, Kaplan JR, Clarkson TB, Bullock BC. Atherosclerosis 1983;48:221-3.)

Oral contraceptive studies

Because endogenous sex hormones and physiologic doses of sex hormones influence atherosclerosis in this species, we also used it to study the effects of contraceptive steroid formulations. We have since completed two studies, which showed that despite these hypothetically atherogenic changes in plasma lipid patterns, oral contraceptive treatment has no adverse influence on coronary artery atherosclerosis.[7,8] We found strong evidence that atherosclerosis was inhibited by combination oral contraceptives containing ethinyl estradiol.

Study 1. In a study reported in 1987, we compared macaques fitted with a vaginal ring containing levonorgestrel and estradiol (n = 13) to others given the oral contraceptive Ovral, norgestrel + ethinyl estradiol (Wyeth-Ayerst, Philadelphia, Pa.) (n = 15) and to untreated controls (n = 15).[7]

Both contraceptive treatments resulted in large reductions in plasma HDL cholesterol concentrations. Neither contraceptive influenced the prevalence of atherosclerosis (percentage of animals with plaque). Animals fitted with the vaginal ring contraceptive showed an increase in the extent of atherosclerosis (plaque area) compared with control animals. In contrast, animals receiving the oral contraceptive had no greater extent of atherosclerosis than did control animals.

These findings suggest that the ethinyl estradiol component of the oral contraceptive neutralized the atherogenic influence of decreased HDL caused by the progestin component. We speculated that estrogen may inhibit the atherosclerotic process through a direct influence on cellular proliferation and metabolism in the arterial intima or through an indirect influence on cellular proliferation or metabolism.

Study 2. Fig. 3 presents the design of the more recent study.[8] A moderately atherogenic diet was fed to 77 female macaques for 31 months.

Methods. During the 7-month preexperimental period, baseline evaluations were made of plasma lipid and lipoprotein variables, after which animals were randomized into three treatment groups by means of a stratification scheme that resulted in equivalence among the groups in regard to pretreatment plasma lipid-risk variables. One group then served as untreated controls, one group was treated with Ovral, and the third group was treated with Demulen, ethynodiol diacetate + ethinyl estradiol (G. D. Searle, Chicago, Ill.).

The oral contraceptives were powdered and mixed

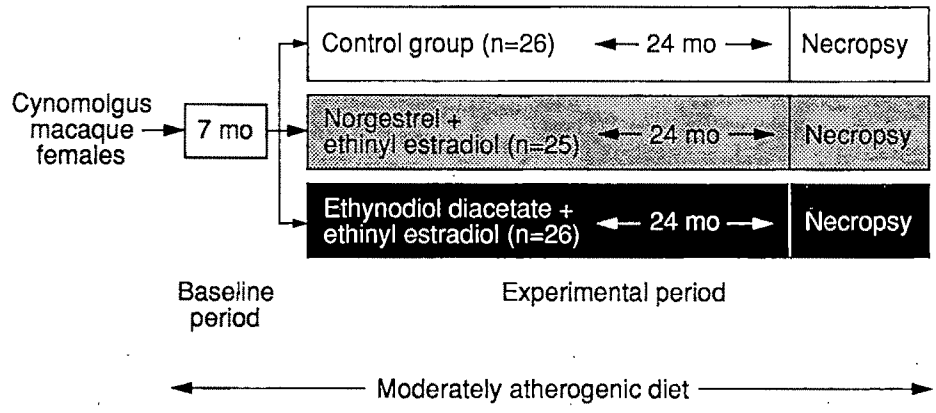

Fig. 3. Design of study to determine the effect of oral contraceptive use on coronary artery atherosclerosis.

Table I. Basis for drug dose

	Cynomolgus macaque		*Woman*	
Average weight (kg)	2.67		50-60	
Calorie consumption (cal/day)	267		1800

Demulen dose/100 cal	55	2.8	55	2.8

Table II. Concentrations of progestins in the circulation 3 to 5 hours after feeding measured at 4- to 6-month intervals

Sampling	*Ovral* (ng/ml) (n = 23)*	*Demulen† (ng/ml) (n = 26)*
Mo 5 (baseline)	ND	ND
Mo 2 (treatment)	2.51 ± 0.83	0.95 ± 0.10
Mo 6 (treatment)	2.46 ± 0.33	0.86 ± 0.18
Mo 12 (treatment)	2.96 ± 0.27	1.06 ± 0.10
Mo 18 (treatment)	2.68 ± 0.34	0.79 ± 0.09
Mo 20 (treatment)	3.57 ± 0.35	1.07 ± 0.12

*Measured as major active metabolite (levonorgestrel).

†Measured as major active metabolite ethynodiol diacetate (norethindrone).

in the diet. The macaque dose was determined from the human dose scaled not by body weight but by species differences in daily caloric consumption (Table I). We chose this method because it is a simple way to adjust for differences in basal metabolic rate, which is higher in the monkey, and because our previous study showed that this dosing method resulted in plasma steroid concentrations similar to those of human beings.

Plasma lipids/lipoproteins were measured throughout the experimental period. After 24 months, necropsies were performed to determine the extent of atherosclerosis. Data were analyzed for all animals and for a subset determined to be at high risk because of hyperlipoproteinemia (total serum cholesterol:HDL cholesterol > 4.5). Multiple regression analysis was used to estimate the difference between predicted effects on coronary artery atherosclerosis caused by the risk factor changes induced by contraceptive steroids and observed effects.

Results. Table II summarizes plasma progestin concentrations, either levonorgestrel or norethindrone (the major metabolite of ethynodiol diacetate), 3 to 5 hours after feeding, measured at 4- to 6-month intervals. Concentrations remained relatively stable over the course of the experiment and in a range similar to values found in women using these formulations.

As in human beings, oral contraceptives affected plasma triglyceride concentrations (Fig. 4). As predicted from differences in the estrogen-progestin balance, the macaques treated with the ethynodial diacetate–containing compound had the highest plasma triglyceride concentrations, whereas untreated control animals had the lowest concentrations.

Predictably, total serum cholesterol concentrations were higher in the two treatment groups compared with the control animals (Fig. 5). The effect was most noticeable in the latter half of the treatment period. Also predictably, HDL cholesterol was lowered by both treatments (Fig. 6). This effect was most pronounced in the norgestrel-containing formulation. The ethynodiol diacetate compound was intermediate between the norgestrel compound and untreated controls.

From Parks JS, Pelkey SJ, Babiak J, Clarkson TB. Contraceptive steroid effects on lipids and lipoproteins in cynomolgus monkeys. Arteriosclerosis 1989;9:261-8. By permission of the American Heart Association, Inc.

The ratio of total serum cholesterol to HDL cholesterol, which is a better predictor of extent of coronary artery atherosclerosis than either alone, was similar in the two treatment groups (Fig. 7). Both treatment groups showed markedly elevated total serum cholesterol to HDL cholesterol ratios compared with controls.

Because it is now thought that the HDL_2 fraction is the component of HDL that provides protection against atherosclerosis, we looked at the HDL heterogeneity or the subfractions and distributions of HDL (Table III). The marked decreases in HDL cholesterol observed in both treatment groups can be largely explained by marked decreases in the HDL_{2b} subfractions. From the lipid and lipoprotein data compiled, we concluded that the changes induced by oral contraceptives were in a direction that would be predicted to have an adverse influence on risk of atherosclerotic coronary heart disease.

The concern that adverse influences of oral contraceptives on coronary heart disease might be magnified in women who are at the highest risk because of adverse plasma lipid profiles led us to determine the effects of treatment in all the macaques and also in a subset (n = 34) considered to be at highest risk because of ratios of total serum cholesterol to HDL cholesterol that were greater than 4.5. In macaques as in humans, risk dramatically increases above this ratio.

Fig. 8 summarizes the effect of treatment on extent of coronary atherosclerosis expressed as plaque size. Coronary intimal area refers to the actual plaque size

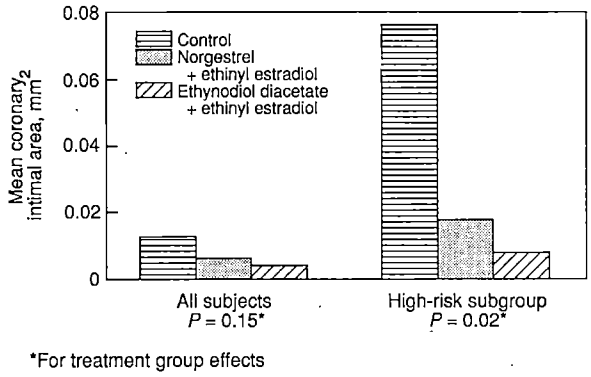

Fig. 8. Effect of treatment on extent of coronary artery atherosclerosis expressed as plaque size. (From Clarkson TB, Adams MR, Shively CA, Koritnik DR. Proceedings of the Consensus Development Conference on Progestogens. Reevaluation of lipid effects on atherosclerosis. Int Proc J 1989;1: 262-6.)

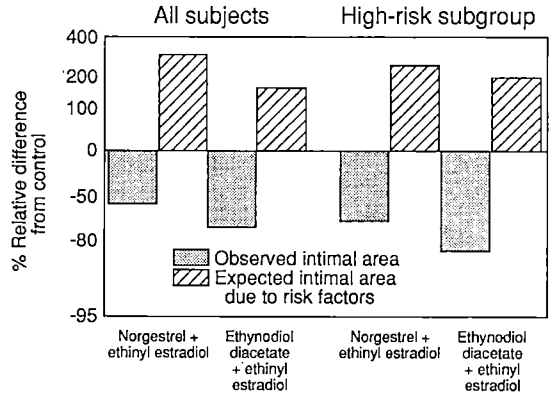

Fig. 9. Observed and expected effects of oral contraception on plasma lipids.

in square millimeters. In both groups, all subjects and the high-risk subgroup, macaques receiving oral contraceptives were less affected than control animals. This difference approached statistical significance in the all-subjects group and was statistically significant among the high-risk animals. There appears to be a large positive or protective effect of oral contraceptives with respect to coronary artery atherosclerosis.

These comparisons did not take into consideration the potential confounding effects of plasma lipid concentrations. Using multiple regression, we were able to predict the effects of oral contraceptives based on changes in plasma lipid levels (Fig. 9). Among all subjects, an approximately twofold increase in extent of atherosclerosis was predicted with each contraceptive formulation. What was observed was a 50% to 75% decrease in extent of atherosclerosis. Among high-risk subjects, the contrast was even more striking. Again, a twofold increase was expected. Instead, a 75% to 85% decrease in extent of atherosclerosis was observed.

Comment

In our studies we found no evidence that combination oral contraceptives have an adverse influence on atherogenesis. In fact, there is strong evidence that oral contraceptives inhibit atherosclerosis, even in the face of marked reductions in plasma HDL cholesterol and especially among high-risk persons. There appears to be a large positive or protective effect of oral contraceptives with respect to coronary artery atherosclerosis.

These studies were done with older, high-dose formulations not in widespread current use. Whether similar effects will be observed with newer, low-dose formulations is unclear. It seems, however, that the estrogen-progestin balance may be important in the protective effect, and although the estrogen dose has decreased in the newer formulations, the progestin dose has decreased proportionally or proportionally more than the estrogen dose. Thus in general the estrogen-progestin balance has not been substantially altered in the new formulations.

Although it remains unknown whether oral contraceptives have similar arterial effects in human beings as in monkeys, the results of our studies are consistent with those of epidemiologic studies of human beings. Although these compounds have been in widespread use for about 25 years, there is no compelling evidence of a widespread adverse influence on coronary heart disease risk. On the contrary, the incidence of coronary heart disease among women in the United States has declined markedly over this same time period. Also, although there is a well-known increase in risk associated with current oral contraceptive use, the increase is very small and not in proportion to effects on plasma lipoproteins.[9] In addition, current evidence indicates that this increase in coronary heart disease risk is largely confined to users of older, high-dose estrogen-progestin formulations who are cigarette smokers.[9] Also, the increased risk disappears after cessation of oral contraceptives[9] thus suggesting a nonatherogenic mechanism such as thrombosis or vasospasm. Furthermore, some studies actually suggest a decrease in the risk of coronary heart disease in past users of oral contraceptives.[9, 10] Taken together, these findings indicate that oral contraceptives probably do not accelerate and may in fact inhibit progression of atherosclerosis in human beings.

We now suspect that in monkeys the antiatherogenic effect of oral contraceptives is accounted for by a direct effect of ethinyl estradiol, the potent estrogen in these formulations, on atherogenesis—an effect that is independent of any changes in plasma lipids. This hypothesis is further supported by findings we have recently made in our laboratory that treatment with estradiol of macaques fed atherogenic diets resulted in marked reduction in the uptake and metabolism of atherogenic low-density lipoproteins by the artery wall

and may thereby directly retard atherogenesis.[11] Although we have not yet studied effects of ethinyl estradiol on this process, it seems reasonable to speculate that it will be even more potent as an inhibitor of low-density lipoprotein uptake. Regardless of the mechanism, we conclude from our findings that contraceptive progestin-induced lowering of HDL is not atherogenic if a sufficiently potent estrogen is coadministered. The striking difference between the expected and observed outcome suggests a beneficial effect of ethinyl estradiol on the coronary wall.

Oral contraceptives and myocardial infarction

Ian H. Thorneycroft, PhD, MD
New Orleans, Louisiana

The risk of myocardial infarction in contraceptive users is limited to women over 35 years of age who smoke. The cause of myocardial infarction in oral contraceptive users is thrombotic and not atherosclerotic. Minor lipid changes have no clinical relevance to myocardial infarction in contraceptive pill users and do not appear to increase coronary plaques. (Am J Obstet Gynecol 1990;163:1393-7.)

Key words: Myocardial infarction, oral contraceptives

A number of both case-control and prospective studies have examined the relationship between oral contraceptives and myocardial infarction. A thorough review of this epidemiologic evidence is not the purpose of this article.[1] The most recent analyses of the Royal College of General Practitioners' Study are reviewed in detail, as are potential mechanisms by which oral contraceptives could cause myocardial infarction. Particular attention is paid to the relevance of lipid studies.

Epidemiology

Early retrospective studies demonstrated approximately a fourfold increase in myocardial infarction in women ingesting oral contraceptives. More recent studies and several prospective studies have not come to the same conclusion.[1] The 1981 analysis of the prospective Royal College of General Practitioners' Study[2] found an increased risk for myocardial infarction in women ingesting oral contraceptives only if they were over the age of 35 years and smoked. The Oxford Family Planning Study[3] found no association with current or past use of oral contraceptives in the analysis of their data published in 1987. They also noted that smokers were at increased risk. The Puget Sound and the Kaiser Walnut Creek studies in the United States failed to confirm an associated risk.[4, 5]

Table I. Royal College of General Practitioners' data: Factors increasing relative risk of myocardial infarction

	Relative risk	*95% confidence interval*
Oral contraceptive use		
Never	1.0

>15/day	3.3*	4.3*	20.8*

Data from Croft P, Hannaford PC. Br Med J 1989;298: 165-8.

*Significant rise.

The most recent analysis of the data of the Royal College of General Practitioners' Study by Croft and Hannaford[6] identified several factors that increase the relative risk of myocardial infarction in young women (Table I). Neither current nor past oral contraceptive users had an increased risk of myocardial infarction. Although current users had a 1.8 times relative risk, the 95% confidence interval includes 1.0. Smoking was a significant risk factor for myocardial infarction. Smoking <15 cigarettes a day led to a 1.7-fold increased risk and >15 cigarettes a day led to a 4.3-fold increased risk. A history of toxemia, hypertension, or diabetes was also a significant risk factor for myocardial infarction.

The data were also analyzed to determine if oral contraceptive use further increased the other known risks of myocardial infarction (Table II). Hypertension and toxemia were again associated with myocardial infarction, but there were no differences among never, former, and current oral contraceptive users. The confidence intervals were wide. More data are needed on any potential interaction between oral contraceptives and hypertension, toxemia, diabetes, and abnormal baseline lipid studies. Current use of oral contraceptives, in combination with smoking >15 cigarettes a day, had the highest high relative risk for myocardial infarction. Oral contraceptive use amplified the risk associated with smoking. These data expand those previously published by the Royal College of General Practitioners, which demonstrated that the real risk factor for myocardial infarction in women using oral contraceptives is smoking. Pills of <50 μg have not been associated with any myocardial infarctions.[3] The differences between early studies and recent analyses are that the early studies did not control for smoking and patients smoking <15 cigarettes a day were classified as nonsmokers.

Table III. Relative risk of major coronary disease among past users of oral contraceptives based on time since last use

If the rate of myocardial infarction was as great as originally estimated (fourfold increase), then mortality studies would clearly show an increased rate of death from ischemic heart disease or myocardial infarction after the introduction of oral contraceptives. Fig. 1 illustrates such data from the United Kingdom.[7] After the introduction of oral contraceptives, cardiovascular disease declined slightly and ischemic heart disease was stable. Therefore no relationship could be found between the introduction of oral contraceptives and heart disease.

Causes of myocardial infarction

Possible causes of myocardial infarction in women ingesting oral contraceptives include increased atherogenesis, increased coronary thrombosis, and coronary artery spasm.

The belief that increased atherosclerosis may cause myocardial infarction is derived from the cholesterol hypothesis. Elevated total and low-density lipoprotein

Fig. 1. (LDL) cholesterol or decreased high-density lipoprotein (HDL) cholesterol are atherogenic and associated with an increased rate of myocardial infarction. Progestins present in oral contraceptives lower HDL and raise LDL cholesterol; all estrogens have the opposite effect. Older, high-dose progestin oral contraceptive preparations were associated with what could be interpreted as adverse changes in lipid profiles.[8] The lipid profile depends on the balance between the estrogen and progestin components. Modern low-dose oral contraceptives are not associated with clinically significant lipid changes.[9] If the mechanism of action of oral contraceptives in increasing myocardial infarction is related to lipid changes, then the following findings should be evident: (1) Past use of oral contraceptives should increase myocardial infarction. (2) The rate of myocardial infarction should increase with increased duration of use. (3) Oral contraceptives should be associated with adverse lipid profiles. (4) These adverse lipid changes should translate into increased coronary artery atherosclerosis. (5) Patients ingesting preparations with adverse lipid changes or a high progestin content should have a higher myocardial infarction rate. (6) Autopsy and angiographic studies should show premature and extensive coronary atherosclerosis.

Table III, which is adapted from the Nurses Health Study,[10] clearly demonstrates that women who used oral contraceptives in the past have no increased risks of myocardial infarction. Nine other studies have demonstrated that past use of oral contraceptives is not associated with an increased rate of myocardial infarction.[10] One study showed a small subset at increased risk[11]; however, Stampfer et al.[10] were not able to confirm that this subset was at greater risk. Table IV illustrates that duration of use also was not related to the incidence of myocardial infarction.

Lipid changes in women ingesting oral contraceptives have been the subject of many publications. Fig. 2 illustrates LDL and HDL levels from selected oral contraceptives from the study of Wahl et al.[8] The vast majority of values from women ingesting oral contraceptives are well within the normal range and unlikely to be atherogenic, even though their mean values may be changed.

Whether adverse lipid changes noted with oral contraceptive use translate into coronary atherosclerosis is

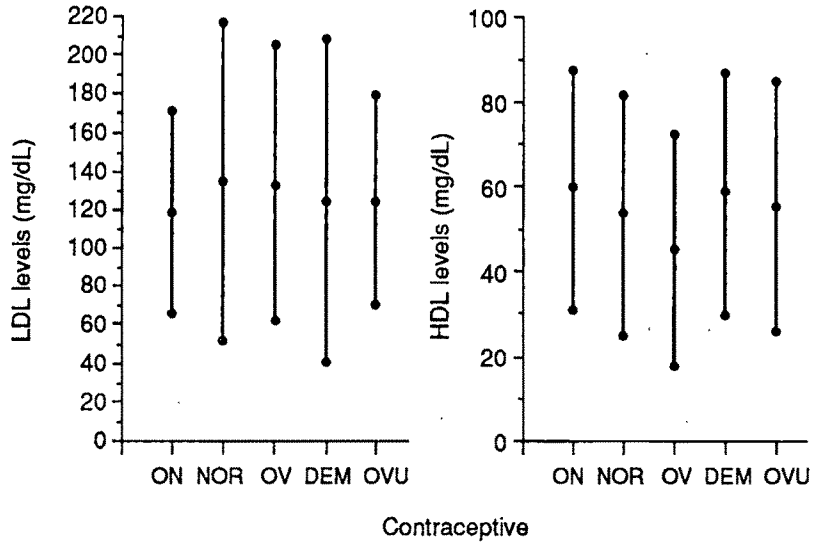

Fig. 2. LDL and HDL levels of selected oral contraceptives (mean ± 2 SD). *ON,* Ortho-Novum, norethindrone + mestranol; *NOR,* Norlestrin, norethindrone acetate + ethinyl estradiol; *OV,* Ovral, norgestrel + ethinyl estradiol; *DEM,* Demulen, ethynodiol diacetate + ethinyl estradiol; *OVU,* Ovulen, ethynodiol diacetate + mestranol. (Data from Wahl P, Walden C, Knopp R, et al. N Engl J Med 1983;30:862-7.)

a difficult question to answer. The elegant cynomolgus macaque studies are reviewed in Adams' presentation in this symposium.[12, 13] Briefly, significant lipid changes were induced in macaque monkeys given oral contraceptive preparations that lowered HDL and raised LDL cholesterol. These lipid changes induced by oral contraceptives did not translate into increased atherogenesis. In fact, the macaque monkeys ingesting oral contraceptives had fewer coronary plaques than did control animals. Such an experiment is not possible in women. However, Engel et al.[14] analyzed coronary angiograms in 76 young women who had suffered a myocardial infarction. Forty-two women used oral contraceptives and 34 did not. Thirty-six percent of women using oral contraceptives had diffuse atherosclerosis, whereas the 79% not using oral contraceptives had diffuse atherosclerosis. Clearly, women undergoing myocardial infarction while taking oral contraceptives did not have atherosclerotic myocardial infarction. Numerous autopsy studies have shown that myocardial infarction in women ingesting oral contraceptives was thrombotic and not atherosclerotic.[14]

Some lipid studies have demonstrated that high-dose levonorgestrel-containing oral contraceptives have the more unfavorable lipid profile. This is not true for all studies. Comparisons between progestins are difficult, because unequivalent doses of progestin and estrogen are usually compared. It is the dose of the progestin and not the specific progestin that affects lipid levels. Croft and Hannaford[15] were unable to find any evidence or examination of their data base to support the hypothesis that levonorgestrel increases the risk of myocardial infarction over other progestins. The relative risk was 0.55 for levonorgestrel and 1.24 for other progestins. The confidence intervals both included 1.0. These differences were not significant. One study showed a dose-response curve between myocardial infarction and the dose of progestin.[16] However, patients did not take the various progestin doses in the same time span. Those patients who ingested the higher doses were probably older, since these were the older preparations. The increased rate of myocardial infarction may simply be the result of the patient's age.

Comment

Myocardial infarctions are extremely rare events in women ingesting oral contraceptives and are usually limited to women over the age of 35 years who smoke. Women who are hypertensive, diabetic, or have a history of toxemia have a higher rate of myocardial infarction. Women with hypertension and toxemia are no more likely to have myocardial infarction if they are ingesting oral contraceptives; however, the confidence limits are large. The risk for persons with diabetes ingesting oral contraceptives is unknown.

The mechanism of action for myocardial infarction in women ingesting oral contraceptives is not atherosclerotic but thrombotic or possibly spasm. Accelerated atherosclerosis is not a characteristic feature in patients with myocardial infarction who use oral contraceptives. Minor lipid changes, noted mainly with oral contraceptives with a high progestin content, may be statistically significant but without clinical significance. It is too simplistic and invalid to extrapolate to oral contra-

ceptive data from epidemiologic studies examining the role of cholesterol in myocardial infarction in men. As Adams et al. demonstrated in their contribution to this symposium, the estrogen component in birth control pills may directly protect the coronary arteries from such atherosclerosis by inhibiting the entry of LDL cholesterol into blood vessel walls.

PART II: A NEW ERA WITH GESTODENE

Clinical acceptability of monophasic gestodene

Bernd Düsterberg and Klaus Brill
Berlin, West Germany

The monophasic low-dose contraceptive containing 30 μg of ethinyl estradiol and 75 μg of gestodene has been tested in numerous clinical studies to determine contraceptive reliability, cycle control, and influence on metabolism and to uncover concomitant symptoms. Clinical data have been derived from continuous phase III studies. Now that the preparation has been introduced in several countries, the opportunity to assemble comprehensive experience has been taken by initiating phase IV studies. Documentation on 600,000 therapy cycles with monophasic gestodene among 100,000 women is already available. The drop-out rate was low. A large number of women participated in the clinical studies for a long time—some up to 3 years. Study results showed that contraceptive reliability was high and cycle control was excellent. The gestodene combination was well tolerated. The frequency of concomitant symptoms was low. The monophasic gestodene meets the basic criteria essential for an oral contraceptive. (Am J Obstet Gynecol, 1990;163:1398-1404.)

Key words: Combination oral contraceptive, contraceptive reliability, cycle control, gestodene

In 1987 a new low-dose combination oral contraceptive agent containing 75 μg of gestodene and 30 μg of ethinyl estradiol (Fig. 1) received its first marketing approval from the German authorities.[1] The preparation is based on the novel progestogen gestodene. Certain advantages are to be anticipated from the clinical application considering the endocrine pharmacologic profile of the compound.

The potent progestational activity of gestodene[2] should provide contraceptive reliability even at extremely low-dose levels. Antiestrogenic properties of the compound can reduce undesirable estrogenic effects in the endometrium and in metabolism.[2] Contraceptive doses of gestodene are virtually without any androgenic activity[2]; thus the occurrence of acne, large increases in body weight, and negative influences on lipid metabolism is unlikely. Finally, the slight antialdosterone effect of gestodene[3] may have some advantages for blood pressure during long-term application. Consequently, the pharmacologic profile of the new progestogen fulfilled all prerequisites for the development of an oral contraceptive based on this progestogen.

The aims of the clinical studies in phases III and IV were above all to examine contraceptive reliability, cycle control, and frequency of concomitant symptoms resulting from treatment with monophasic gestodene. These factors, in addition to the well-known beneficial effects of oral contraceptives, may have an influence on the acceptability of the compound (Fig. 2). In this context, compliance must be considered. It can be assessed to some extent by the drop-out rate in clinical trials.

Material and methods

Subjects and design of trials. Healthy, sexually active female volunteers, ideally <35 years of age, were asked to take the preparation for periods varying between 6 and 36 cycles in the different studies. Each volunteer provided informed consent and was considered to have sufficient intelligence and motivation to follow instructions and continue the studies for the anticipated periods of observation. They were screened for contraindications to the use of oral contraceptives. A complete history and physical examination were performed before they entered the trial. Follow-up evaluations were performed regularly throughout the trial periods according to the trial protocols.

Sizes of clinical trials. The sizes of seven multicenter phase III studies are shown in Table I.[4-9] The trials were conducted mainly in European and in some Latin American countries according to local institutional regulations. The number of women recruited and consequently the number of cycles covered varied considerably. In total 6854 women participated in 69,978 cycles of treatment with monophasic gestodene in phase III studies.

In addition, data have been obtained on 523,477 cycles in 95,906 women participating in a phase IV study.[10] This trial was performed in Germany according to German regulations. This means that for this type of trial, the most relevant conditions—for instance, the

trial protocol, the record forms, and the performance of the trial in general—are comparable with those of the phase III studies.

Results

Contraceptive reliability. Few pregnancies were recorded in any of the phase III studies and the phase IV trial (Fig. 3). Despite incidences of one to eight or more missed tablets in many of the cycles in the various studies, pregnancies occurred in only three out of eight trials. Most of these pregnancies were attributable to

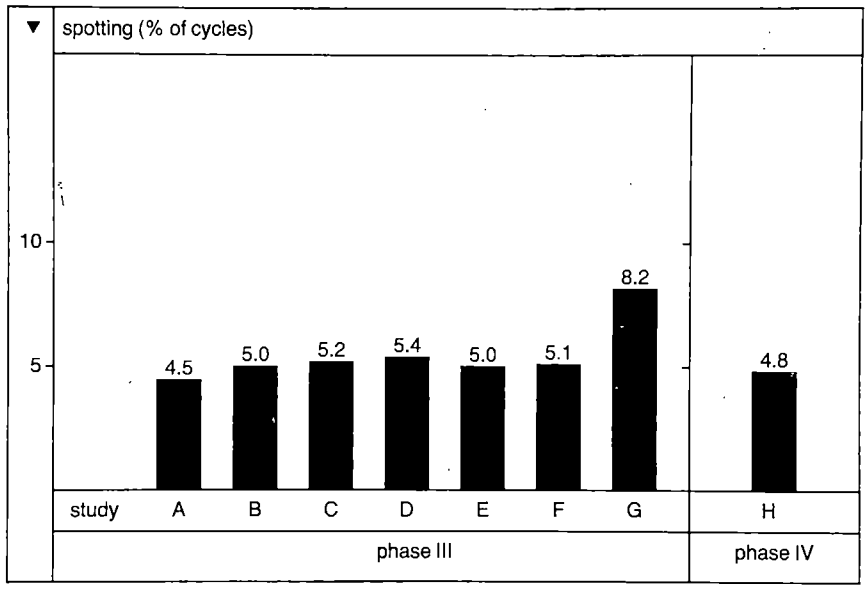

Fig. 5. Spotting rate during treatment with monophasic gestodene.

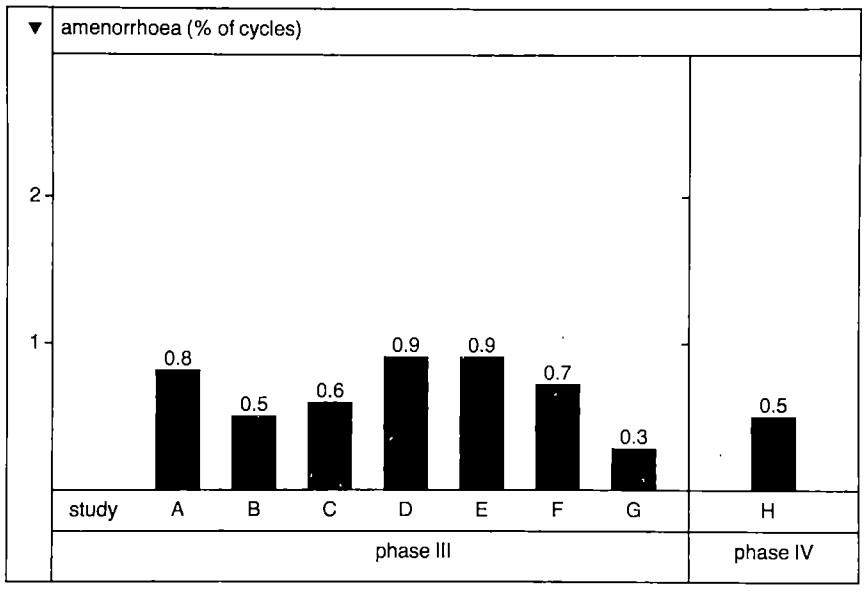

Fig. 6. Amenorrhea rate during treatment with monophasic gestodene.

errors in tablet taking. Some pregnancies were presumed to be from method failures.

Based on the most comprehensive phase III trial covering 36,721 cycles in 3267 women and the maximum observation period of 18 months, the Pearl index (as a measure of contraceptive reliability) was 0.07 for tablet failures and 0.16 for user failures (Table II).[4] Thus the uncorrected Pearl index is about 0.2, a value confirmed by the phase IV trial. Although monophasic gestodene has an extremely low steroid content, its efficacy is as good or better than that of most currently available low-dose preparations.[9]

Cycle control. Bleeding irregularities were recorded as "breakthrough bleeding" when the quantity required sanitary protection and as "spotting" when the amount was tolerable without such protection. The frequency of intracyclic bleeding was very low during treatment with monophasic gestodene. Breakthrough bleeding was reported in 0.6% to 2.8% of the cycles documented in the trials (Fig. 4). Spotting occurred for an incidence of 4.5% to 8.2%, mainly during the first cycles of use (Fig. 5). Amenorrhea, which was defined as an absence of bleeding during the tablet-free interval, was recorded in <1% of the cycles (Fig. 6).

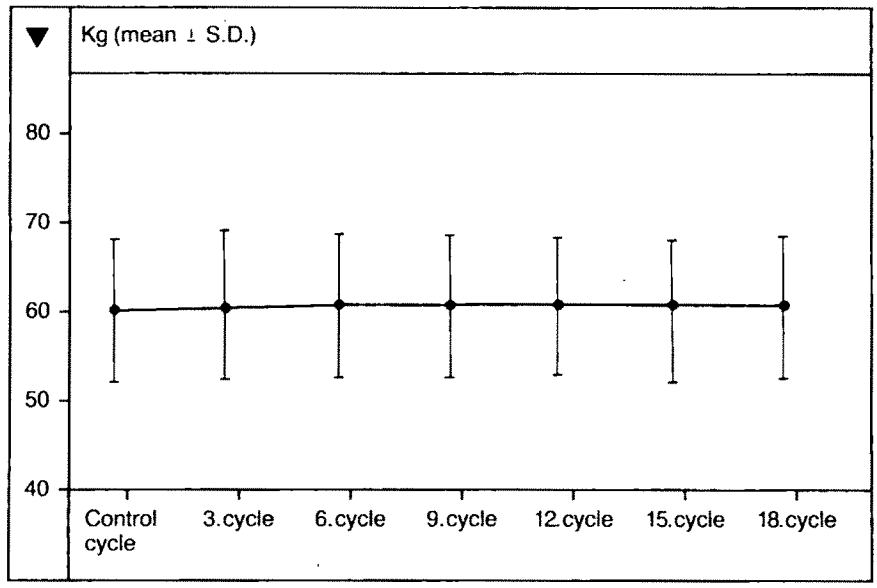

Fig. 7. Body weight changes during treatment with monophasic gestodene (phase III trial, $n = 3267$).

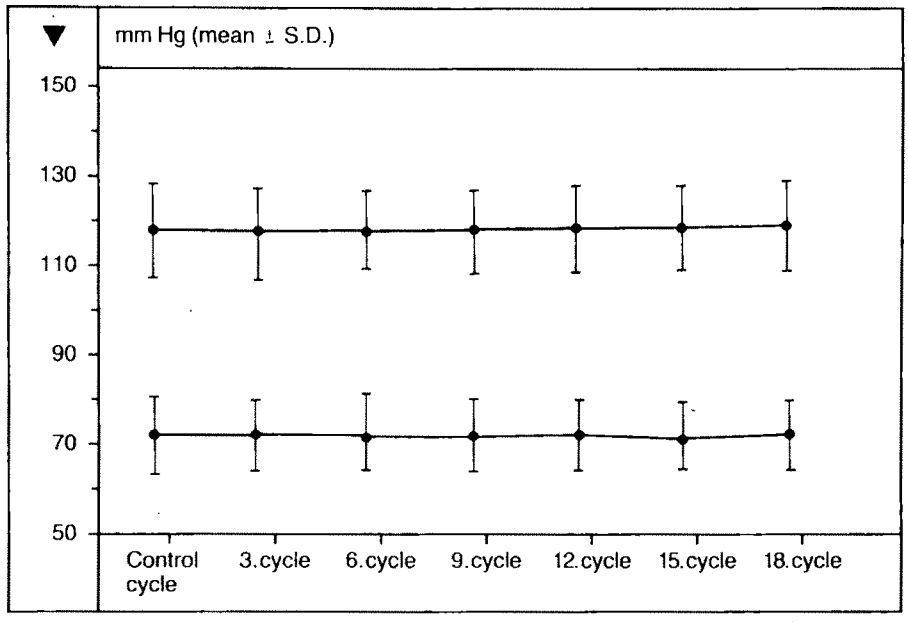

Fig. 8. Blood pressure changes during treatment with monophasic gestodene (phase III trial, $n = 3267$). (From Brill K, Schnitker J, Albring M. Langzeiterfahrungen mit dem niedrigdosierten Ovulationshemmer Femovan. Gyne 1989;2:47-50.)

Incidence of concomitant symptoms. Overall, the incidence of concomitant symptoms reported by the women during the trials was very low. As shown in Table III, only breast tension, headache, nausea, nervousness, dizziness, and depression were recorded in >1% of the women after six cycles of monophasic gestodene use. Nausea and vomiting occurred fairly frequently in the initial cycles of use and dropped thereafter. The frequency of breast tension and headaches remained around the pretreatment level. Migraine-type headaches and varicose disorders were practically uninfluenced.

Acne and edema were recorded as objectifiable symptoms in a few cases (Table III). Regarding the number of women still participating in the study at the respective times of assessment, there was a continuous decline in the rate of acne. The number of cases of edema dropped continuously with the progressing trials.

Body weight and blood pressure. Monophasic gestodene had essentially no pronounced effects on body weight in most women. As a representative example of the results of all trials, the findings of the largest phase III study are presented.[4] The mean values of body weight changed only by a maximum of 0.2 kg in the

study population. No significant weight gain could be attributed to the oral contraceptive (Fig. 7).

Similarly, blood pressure remained stable and within normal clinical limits in the eight trials. In all but a very few instances, pretreatment levels were measured throughout the studies. At no time was there an indication that monophasic gestodene had any effect on systolic or diastolic blood pressure. The data of the different trials are consistent; the results of the phase III study illustrate the findings (Fig. 8).

Discontinuation rates. Drop-out rates for medical reasons are shown in Fig. 9. Of the women enrolled in the trials, between 4.7% and 25.5% discontinued the monophasic gestodene for different medical reasons. Usually the drop-out rate was about 10% or even less than 10%. Study F had been performed in a family planning clinic in very young women. Probably the different contraceptive behavior of these young women contributed to the drop-out rate.

Generally the most frequently reported complaints were spotting and breakthrough bleeding, which were seen in a maximum of 5% of participants. Weight gain and headaches led to a drop-out rate of 2% to 4%. Less than 2% of the women reported nausea or breast tension. Other events were very rare; the rate for all of these was <1% of the women enrolled.

Comment. Cycle control of monophasic gestodene was excellent. The incidence of concomitant symptoms commonly associated with the use of oral contraceptives was minimal. Mean body weight and blood pressure showed virtually no changes.

The participants' acceptance of the new preparation was remarkably high. Only about 10% of the women discontinued the monophasic gestodene for medical reasons. It can be concluded from data obtained in about 100,000 women and 600,000 cycles of use that monophasic gestodene is an effective and well-tolerated oral contraceptive.

Inhibition of ovulation by low-dose monophasic contraceptive containing gestodene*

Karl Thomas, MD, and Leo Vankrieken, BSc

Brussels, Belgium

Ovulation inhibition by the monophasic oral contraceptive containing 75 μg of gestodene and 30 μg of ethinyl estradiol was evaluated in 25 healthy volunteers for five cycles: a pretreatment cycle, three treatment cycles, and a posttreatment cycle. Serum luteinizing and follicle-stimulating hormones, estradiol, and progesterone levels were measured on days 8 through 17; progesterone was measured once, around day 21. Pelvic ultrasound examinations were performed on cycle days 6, 8, 10, 12, 14, and 16. In 18 subjects completing the study, luteinizing and follicle-stimulating hormone levels were strongly depressed in the treated cycles. From treated cycle days 8 to 17, luteinizing and follicle-stimulating hormone levels reached values on the lower limit of detection. Luteal activity was not detected in treated cycles. Follicular activity, which was reflected by estradiol levels, was most strongly depressed during the first treated cycle. Pelvic ultrasound examinations confirmed excellent inhibition of follicular maturation. Restoration of ovarian function in the posttreatment cycle was excellent and showed a midcycle hormonal profile identical to the pretrial cycle. (Am J Obstet Gynecol 1990;163:1404-10.)

Key words: Gestodene, oral contraception, ovulation inhibition

Gestodene is probably the most powerful synthetic gestogen currently used in humans. Consequently, it contributes to the development of very efficient hormonal progestogen-estrogen combinations for oral contraception. Nevertheless, the impact of recent hormonal contraceptive formulations containing gestodene on the hypophysial-ovarian axis,[1, 2] whose principal goal is the suppression of ovulation, needs more extensive documentation, because essentially only their metabolic effects have been carefully studied.[3] Therefore this study was undertaken of a low-dose monophasic contraceptive containing gestodene and ethinyl estradiol to evaluate the impact on the hypophysial-ovarian axis in a group of young ovulating women.

Material and methods

Twenty-five healthy volunteers, ages 27 ± 0.9 years (mean ± SEM), with a mean cycle length of 28.2 ± 0.6 days (mean ± SEM), were selected for the study. Each subject was followed during eight consecutive cycles: a pretreatment control cycle when no medication was given, six cycles when medication was given, and a posttreatment recovery cycle. A contraceptive preparation containing 75 μg of gestodene with 30 μg of ethinyl

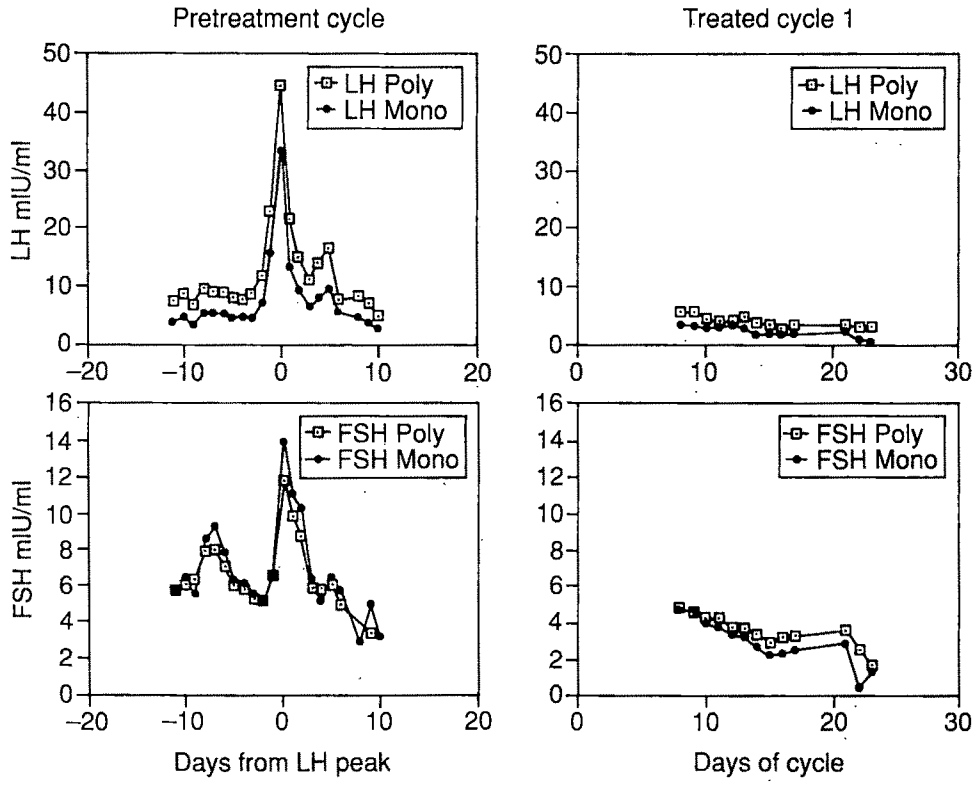

Fig. 1. Mean plasma LH and FSH concentrations measured by polyclonal and monoclonal RIA techniques in eight volunteers during pregnancy and first treatment cycles.

estradiol per daily dose was administered for 21 consecutive days during the treatment cycles, followed by a 7-day pill-free interval.

Plasma luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol, and progesterone levels were assayed daily from cycle days 8 through 17 in the pretreatment cycle; treatment cycles 1, 3, and 6; and the posttreatment cycle. In addition, during the same cycles, progesterone was assayed once again at around cycle day 21, and pelvic ultrasound examinations were performed on days 6, 8, 10, 12, 14, and 16.

Of the 25 volunteers who began the study, 7 dropped out. Three were unable to come regularly for follow-up, two showed no signs of ovulation during the control cycle and therefore were excluded from the study, one dropped out after she became pregnant during the control cycle, and the seventh dropped out because of continuous spotting. All the results presented in this study are derived from the 18 volunteers who completed the entire study.

Blood plasma LH and FSH levels were assayed with polyclonal radioimmunoassay (RIA) systems (Amerlex, Amersham, England). Progesterone and 17 β-estradiol levels were assayed by classic RIA systems (Medgenix, Brussels, Belgium). In eight of the volunteers, plasma LH and FSH levels were simultaneously assayed by a monoclonal RIA system (Medgenix, Brussels, Belgium) during the pretreatment and first treatment cycles to compare the polyclonal and monoclonal RIA systems.

Ultrasound investigation of the ovaries was performed with a 3.5 MHz Diasonics DRF 100 sector scanner by means of the full bladder technique and the transabdominal approach. The diameters of the follicle structure were measured in both longitudinal and transverse planes from which the mean was calculated.

Results

The results obtained from the comparative study of the monoclonal and polyclonal RIA systems are shown in Fig. 1. In both the pretreatment and first treatment cycles, the fluctuations in mean LH levels obtained by the two systems are perfectly parallel to one another. As expected, the monoclonal values were somewhat lower but not statistically significantly different from those obtained with the polyclonal system. A similar situation is observed with the FSH assays, but the results are strictly superposable. This preliminary comparison validated the further use of only a polyclonal RIA system to establish our results.

Figs. 2 and 3 show the mean LH and FSH profiles of the 18 volunteers during the five explored cycles.

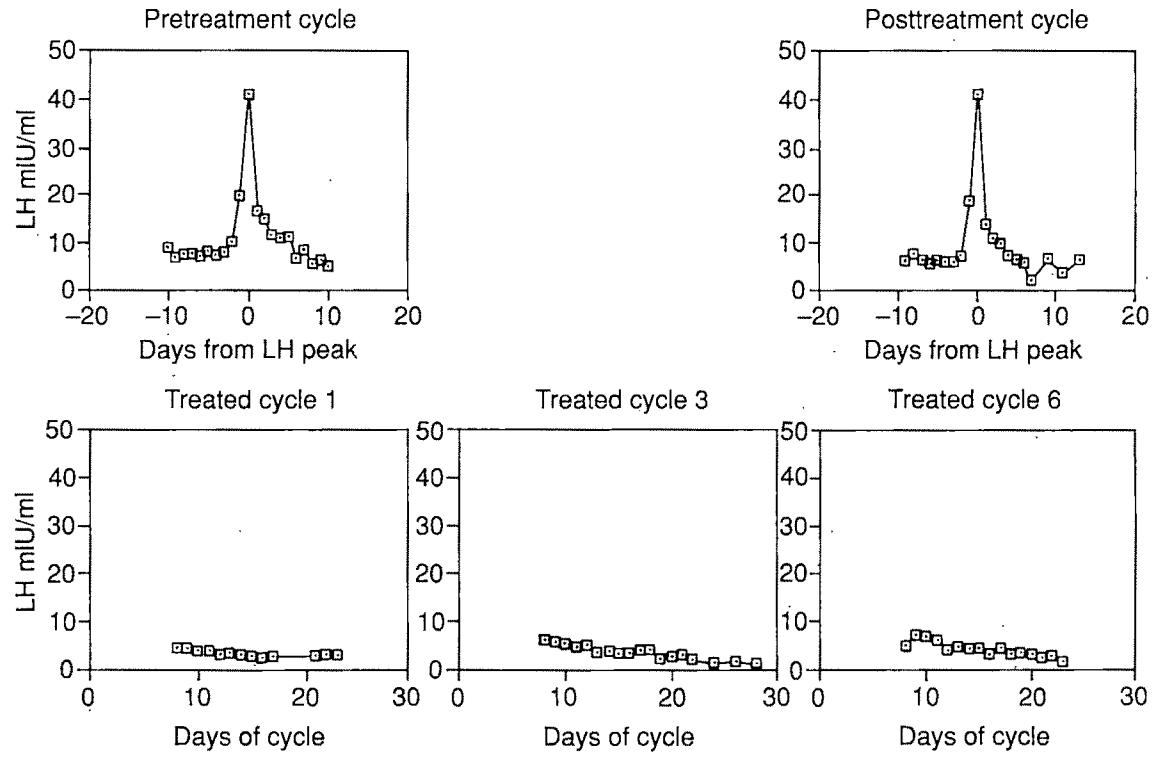

Fig. 2. Mean plasma LH levels in 18 volunteers during pre- and posttreatment cycles and during treatment cycles 1, 3, and 6 (75 μg of gestodene + 30 μg of ethinyl estradiol).

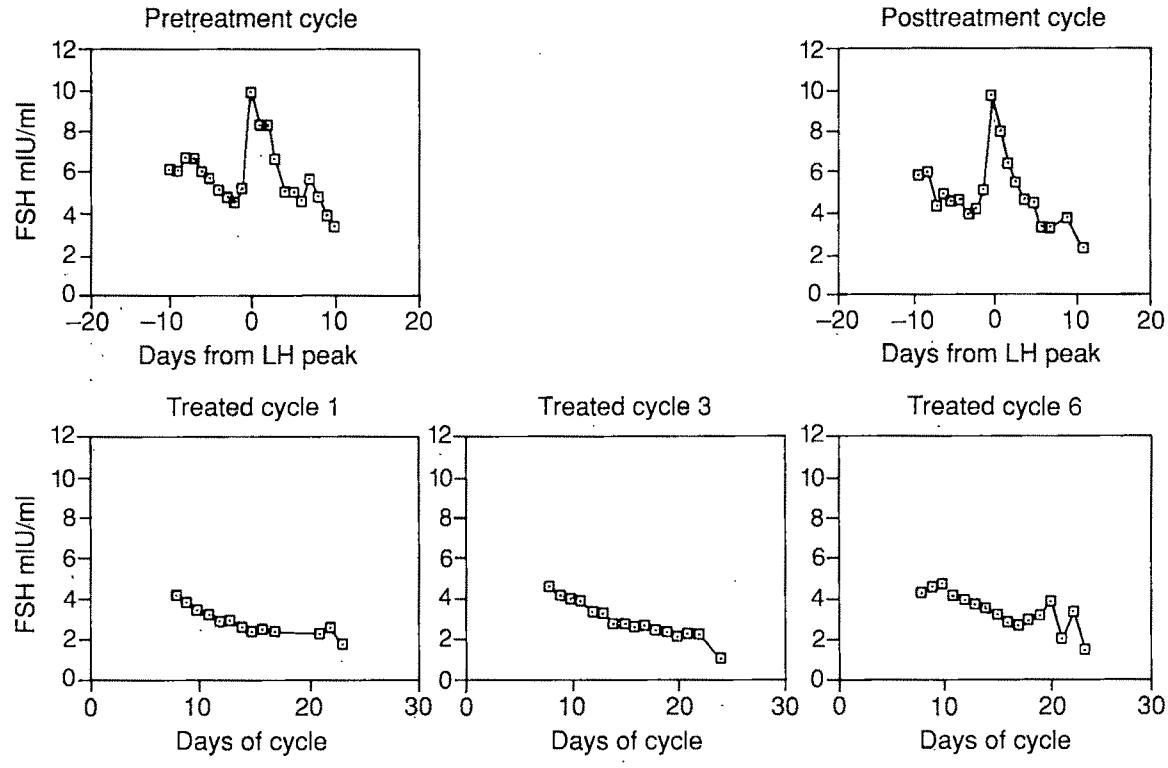

Fig. 3. Mean plasma FSH levels in 18 volunteers during pre- and posttreatment cycles and during treatment cycles 1, 3, and 6 (75 μg of gestodene + 30 μg of ethinyl estradiol).

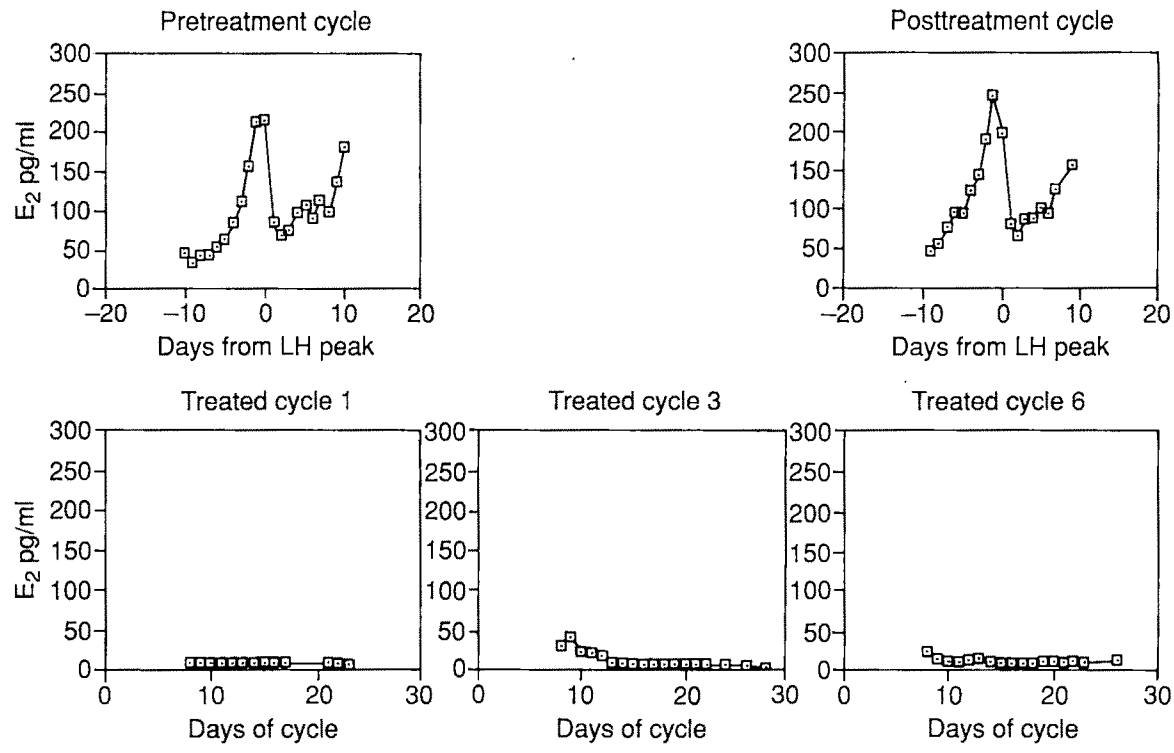

Fig. 4. Mean plasma 17-β estradiol levels in 18 volunteers during pre- and posttreatment cycles and during treatment cycles 1, 3, 6 (75 μg of gestodene + 30 μg of ethinyl estradiol).

For LH a complete suppression of the midcycle peak during the treatment cycles and its immediate reappearance in the posttreatment control cycle are observed. In the case of FSH secretion, the characteristic profile also disappears during the treatment cycle and again it reappears during the posttreatment control cycle.

A strong inhibition of estradiol secretion is already apparent in the first treatment cycle (Fig. 4). Again, a normal cyclic profile reappears as soon as treatment is stopped in the posttreatment cycle. Similar remarks may be made concerning the progesterone profiles (Fig. 5), in which total suppression of luteal activity was observed during treatment.

The hormone concentrations appear to have reached apparent stable suppressed values during the treatment cycles. If the hormonal concentrations during the treatment cycles are plotted on an expanded scale (Fig. 6), we can observe the impact of treatment not only on the characteristic hormonal fluctuations of the ovulatory cycle, as shown in Figs. 2 through 4, but also demonstrate that basal levels were significantly affected. In LH and FSH, a progressive significant decrease in concentration was clearly present in cycle 1 and to the same degree in treatment cycles 3 and 6.

However, the expanded scale for estrogens, shows a somewhat different pattern. During the first treatment cycle, nearly all serum estradiol concentrations are <25 pg/ml. However, in contrast, in the third and sixth treatment cycles, an elevated estradiol level was observed during the first few days of the hormonal investigation. For progesterone, the concentrations remain within stable limits during the treatment period (Fig. 5).

Fig. 7 shows the distribution of maximal 17β-estradiol (pg/ml) in each individual investigated cycle of the 18 volunteers. In the pre- and posttrial cycles, nearly all estradiol concentrations are in the mature follicular range values. In contrast, estradiol concentrations are strongly depressed (<25 pg/ml) in nearly all treatment cycles. However, in cycles 3 and 6, a few volunteers showed slight follicular activity and one even showed a high estradiol level.

The results of the ultrasound investigation of the ovaries are shown in Fig. 8. Here the data are expressed as the maximal follicular diameter, this from the leading follicle, measured in each investigated cycle. Again, the ovaries of pre- and posttreatment cycles show mature preovulatory follicles except in two cases in the posttreatment cycle, in which the follicular maturation was somewhat retarded. During all treatment cycles, follicular growth was blocked around 10 mm diameter

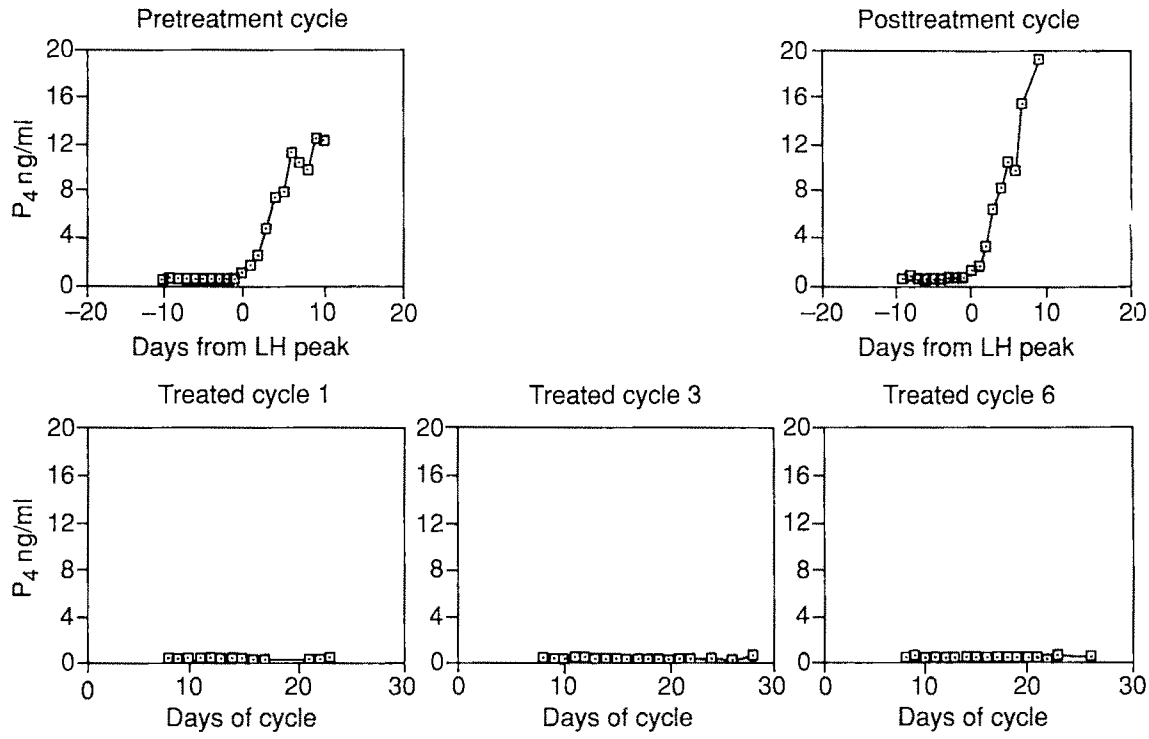

Fig. 5. Mean plasma progesterone estradiol levels in 18 volunteers during pre- and posttreatment cycles and during treatment cycles 1, 3, and 6 (75 μg of gestodene + 30 μg of ethinyl estradiol).

and only one in the third treatment cycle grew 12.5 mm. This exception is the same woman who had a high estradiol level during the third treatment cycle, as shown in Fig. 7. However, as with all the other volunteers, this woman did not develop any luteal activity during treatment.

Whereas oral contraceptives containing 75 μg of gestodene and 30 μg ethinyl estradiol have no clinically relevant influence on lipids, carbohydrates, and blood clotting,[3] from the foregoing evidence we can conclude that the impact on the hypophysial-ovarian axis results in a strong inhibition of this axis and consequently ovulation. The data of our study may be summarized as follows:

1. There is complete suppression of the midcycle LH surge and complete suppression of the characteristic fluctuations in FSH. Furthermore, from the first treatment cycle, basal levels of LH and FSH clearly show a progressive and significant decrease; this continues to be observed to the same degree in treatment cycles 3 and 6, thus demonstrating the efficacy of the formulation on basal gonadotropin secretion from the beginning of treatment.
2. Excellent blockage of follicular maturation is observed by ultrasonic assessment of the ovaries. This is further confirmed by very low plasma estradiol levels. However, the expanded scale of estrogen levels in the third and sixth treatment cycles shows slightly elevated estradiol levels in the first days of the hormonal investigation. This suggests that in a few volunteers follicular maturation may have already been initiated during the 7-day pill-free interval. This is not observed in the first treatment cycle when the volunteers begin treatment on the first day of menstruation. The pos-

sibility that follicular activity was initiated in some women, as observed in a few of our volunteers, during the third and sixth treatment cycles, raised the problem of the ideal length of the pill-free interval. The 7-day pill-free interval should be considered the maximum permitted. This problem is all the more acute because of the forgetfulness of some users. On the other hand, it has been shown that a 2-day interruption in the intake of this formulation failed to produce any marked increase in ovarian activity.[4]

3. The strong inhibition of ovarian secretion is also reflected by total suppression of all luteal activity, even in the few patients in whom the initiation of follicular maturation was observed.
4. Finally, it was remarkable to observe that the normal hormonal profile was completely restored during the immediate posttreatment cycle.

Comment

Our data show that the gestodene–ethinyl estradiol combination, when correctly administered in healthy women, effectively inhibits the hypophysial-ovarian axis, thus providing absolute contraceptive security despite the low dosage of the components.

Effects of oral contraceptives on lipid metabolism

Jan A. Gevers Leuven, MD, PhD, Marianne C. Dersjant-Roorda, Frans M. Helmerhorst, MD, PhD, Rinse de Boer, MD, Angela Neymeyer-Leloux, MD, and Louis M. Havekes, PhD

Leiden and Hertogenbosch, The Netherlands

A randomized, comparative study of two low-dose oral contraceptives was carried out in 60 nonpregnant women for 12 cycles. Twenty-eight women took a preparation containing 150 μg of desogestrel and 30 μg of ethinyl estradiol; 32 took 75 μg of gestodene and 30 μg of ethinyl estradiol. Baseline values in the two groups were in good agreement. During the first three cycles, serum cholesterol levels remained unchanged, but triglyceride and high-density lipoprotein cholesterol levels increased significantly and to the same extent (about 20%). Low-density lipoprotein cholesterol levels decreased slightly. Apolipoproteins A_1 and A_2 and low-density lipoprotein B increased significantly and similarly. Except for continued increases in low-density lipoprotein B, no further changes were noted during subsequent cycles. We concluded that the two contraceptives have the same impact on lipid metabolism, with all lipid and apolipoprotein values remaining within the normal range. The changes with both pills reflect a mild estrogenic dominance. Implications for coronary artery atherosclerosis appear to be minimal. (Am J Obstet Gynecol 1990;163:1410-3.)

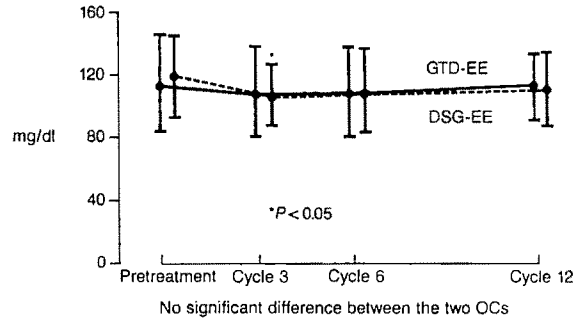

Fig. 3. Mean low-density lipoprotein cholesterol values (± standard deviation) before and during the use of oral contraceptives. (*GTD-EE*, 75 μg gestodene + 30 μg ethinyl estradiol; *DSG-EE*, 150 μg desogestrel + 30 μg desogestrel + 30 μg ethinyl estradiol.)

lesterol is causally associated with an inhibition of atherogenesis is less complete.

Fig. 1 is a simplified scheme of lipoprotein metabolism.[3] In the liver triglyceride synthesis is enhanced by estrogen and inhibited by androgen. This triglyceride is brought into the circulation in particles called very low-density lipoproteins, so these particles are filled with endogenous triglyceride. The synthesis rate of its carrier protein, apolipoprotein B, is also enhanced by estrogen.

In the circulation very low-density lipoproteins are cleared by fat-consuming tissues (such as the heart muscle) and stored in adipose tissue. When triglyceride is removed, the particles shrink, so core remnants are smaller than very low-density lipoproteins. They are brought into the circulation again. These core remnants still contain apolipoprotein B. Liver lipase finally converts them to low-density lipoproteins. The low-density lipoprotein still contains the same amount per particle of apolipoprotein B.

In contrast, surface remnants that are also formed during the clearance of very low-density lipoproteins enter the circulation and are converted into high-density lipoproteins. Estrogen enhances the synthesis of their major carrier protein, apolipoprotein A. Liver lipase is probably involved in the removal of cholesterol from high-density lipoproteins. Lipolytic activity of liver lipase is inhibited by estrogen and enhanced by androgen. Progestogens may have antiestrogen and androgen side effects. When a contraceptive pill containing an estrogen and a progestogen is introduced, as in the study described herein, the resultant effect is not predictable.

Material and methods

A fuller discussion of this study is contained in an article published previously in this JOURNAL.[3] The study enlisted 60 healthy, nonpregnant women between the ages of 20 and 35 years. Most had not previously used an oral contraceptive and none had used one within

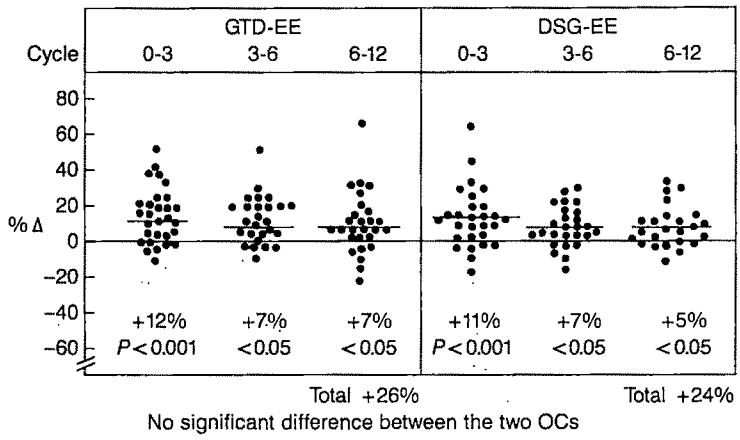

Fig. 4. Individual variations in low-density lipoprotein apolipoprotein B levels from pretreatment to treatment cycles 3, 6, and 12. the past 3 months. The subjects were randomized into two groups: 32 were given 75 μg of gestodene and 30 μg of ethinyl estradiol; 28 women were given 150 μg of desogestrel and 30 μg of ethinyl estradiol. Fasting blood samples were taken between the seventeenth and twenty-fifth day of the pretreatment cycle and between the eighteenth and twenty-second days of cycles 3, 6, and 12. Informed consent was obtained. The committee on medical ethics of the University of Leiden had approved the study.

Results

Triglycerides. When measured pretreatment, triglyceride levels for the two groups were the same (Fig. 2). Through cycle 3, triglyceride levels increased close to the classic level that would be predicted based on the estrogenic effect. After that triglyceride values leveled off.

Low-density lipoprotein cholesterol. Introduction of either oral contraceptive did not lead to an increase in low-density lipoprotein cholesterol (Fig. 3). With the desogestrel-containing combination, there was actually a slight but significant decrease in these levels during the first three cycles.

The carrier lipoprotein of low-density lipoprotein, apolipoprotein B, increased to a significant degree in every period of observation for both contraceptives (Fig. 4). Overall between pretreatment and the twelfth cycle, apolipoprotein B levels increased 26% with the gestodene formulation and 24% with the desogestrel formulation. This is not a significant difference between the two formulations, but the fact that apolipoprotein B levels were increasing was worthy of concern.

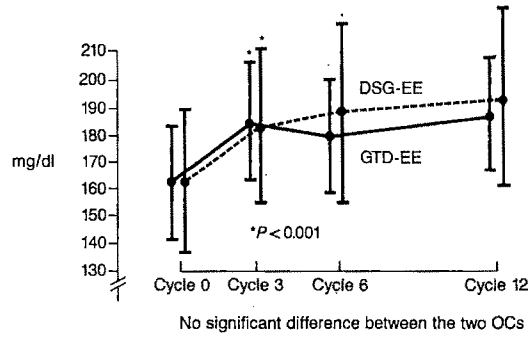

Fig. 7. Mean apolipoprotein A_1 values (± standard deviation) before and during use of oral contraceptives. (*DSG-EE*, 150 μg desogestrel + 30 μg ethinyl estradiol; *GTD-EE*, 75 μg gestodene + 30 μg ethinyl estradiol.)

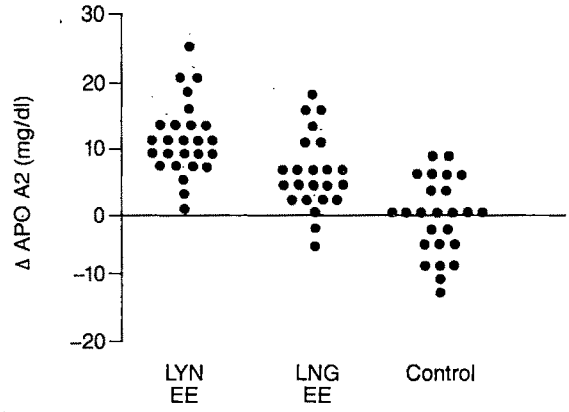

Fig. 8. Effect of oral contraceptives on apolipoprotein A_2. (*LYN-EE*, 750 μg lynestrenol + 37.5 μg ethinyl estradiol; *LNG-EE*, 150 μg levonorgestrel + 30 μg ethinyl estradiol.)

This increase is not unique to these two formulations. When we studied two other combination pills, one containing 750 μg of lynestrenol and 37.5 μg of ethinyl estradiol and the other 150 μg levonorgestrel and 30 μg of ethinyl estradiol, we also observed increases in apolipoprotein B compared with untreated controls (Fig. 5).[4] We suspect the increase in apolipoprotein B is an estrogenic effect.

High-density lipoprotein cholesterol. For both formulations, high-density lipoprotein concentrations increased significantly at a similar rate from pretreatment to cycle 3 (Fig. 6). After cycle 3 the concentrations for both formulations leveled off, albeit with some fluctuation.

Baseline apolipoprotein A_1 values for the formulations were the same, and both showed a comparable, highly significant increase at cycle 3 (Fig. 7). Apolipoprotein A_1 values for the desogestrel combination continued increasing through the balance of the cycles. After a drop between cycles 3 and 6, apolipoprotein A_1 values for the gestodene combination resumed increasing. We only have preliminary data on apolipoprotein A_2 values for these two formulations. However, evidence from our comparison of combination formulations containing lynestrenol or levonorgestrel showed clear increases in apolipoprotein A_2 values over control values (Fig. 8). Apolipoprotein A_2 values were highest in the lynestrenol combination, which contained a larger estrogen component (37.5 μg versus 30 μg ethinyl estradiol).

Comment

From our accumulated evidence to date, we conclude that all mean values of lipoprotein levels increased significantly in users of low-dose oral contraceptives. These changes indicate a mild estrogenic dominance in all four low-dose oral contraceptives we examined in our two studies.

On the basis of current knowledge, it seems unlikely that changes in the estrogen/(antiestrogen + androgen) balance induced by oral contraceptives increase cardiovascular risks. The rise in triglyceride levels is probably of little, if any, relevance.[5] The possible increased risk caused by the rise in apolipoprotein B, which has been observed in studies in men,[6] even if it applies to women, would appear to be offset by the decrease in risk resulting from the increase in apolipoproteins A_1 and A_2.[7]

We thank H. A. Th. de Pagter for her skillful administrative work and P. C. M. de Wit, A. E. M. Kramp, and H. A. van der Voort for skillful technical assistance.

Pharmacokinetics of gestodene and ethinyl estradiol after oral administration of a monophasic contraceptive

Ulrich Täuber, PhD, Wilhelm Kuhnz, PhD, and Michael Hümpel, PhD
Berlin, West Germany

The pharmacokinetic and protein-binding properties of gestodene and ethinyl estradiol have been investigated after single and multiple dosing in several studies in 83 healthy, young women. After oral administration, gestodene is completely absorbed and bioavailable and exhibits dose-linear pharmacokinetics. During long-term pill use, serum levels of gestodene were four to five times higher than after single administration, showing a periodic increase from day 1 to day 10 during each cycle. Ultrafiltration studies revealed that 75.3% of total serum gestodene is bound to sex hormone–binding globulin, 24.1% is bound to albumin, and only 0.6% is not protein bound. Thus gestodene levels during steady state are explained by an increase in sex hormone binding–globulin as a result of concomitant administered ethinyl estradiol and a specific binding of gestodene to this protein. Serum levels of ethinyl estradiol during single and multiple administration were identical and were not different from those observed with another preparation containing 30 μg of ethinyl estradiol. (AM J OBSTET GYNECOL 1990;163:1414-20.)

Key words: Ethinyl estradiol, gestodene, monophasic contraceptive

Progestins and estrogens in oral contraceptives are either drugs, which are, per se, pharmacologically active, or prodrugs, which must be converted into the active compound by the organism. Most progestins used in oral contraception are of the 19-nortestosterone type (Fig. 1). Norethisterone, as the first compound available, is still one of the most widely used progestins and is the active principle of several prodrugs (norethisterone acetate, norethynodrel, ethynodiol diacetate, and lynestrenol).

Changing the methyl residue at C13 to an ethyl group led to norgestrel and its solely active enantiomer levonorgestrel (D (−) norgestrel), whose progestogenic activity is approximately 10-fold higher than that of norethisterone.[1-3] The progestins of the so-called third generation are desogestrel, norgestimate, and the latest development, gestodene. Desogestrel and norgestimate are both prodrugs. Desogestrel is activated in the body by conversion into 3-ketodesogestrel; norgestimate is converted by biotransformation into several metabolites—one, of which the most important is probably levonorgestrel.

After oral administration of a contraceptive pill, a series of events precede or run in parallel while the active ingredients reach their site of action. A necessary prerequisite for drug absorption is the disintegration of the tablet in the gastrointestinal tract and the dissolution of the active ingredients. After absorption and first passage in the liver, the active ingredients are bound to transport proteins in the plasma and are distributed throughout the body by way of the circulation. Parallel to these distribution processes, the compounds are metabolically degraded and excreted with the urine and the bile. Pharmacokinetics describes these processes quantitatively by monitoring drug and metabolite levels in blood and excreta.

This article presents the pharmacokinetic behavior of gestodene in humans.

Material and methods

Subjects and design of trials. Tables I and II summarize the most important pharmacokinetic studies with gestodene in human volunteers.

Single-dose studies. In the single-dose study by Düsterberg et al., absorption, distribution, biotransformation, and excretion were investigated after intravenous and oral administration of 50 and 500 μg of carbon 14–gestodene (^{14}C-label in the ethinyl group) as a solution in propanediol physiologic saline solution (10/90 v/v) and as micronized substance together with lactose.

In the study by Täuber et al.,[5] basic pharmacokinetic parameters of gestodene, absolute bioavailability, and dose linearity of pharmacokinetics were investigated in a fourfold changeover design in six young women. In a third trial plasma levels of ethinyl estradiol were studied in 18 young female volunteers receiving a single dose of Femovan (gestodene, 75 μg + ethinyl estradiol, 30 μg; Schering Ag, Berlin, West Germany) and Marvelon (desogestrel, 150 μg + ethinyl estradiol, 30 μg; Organon, Oss, The Netherlands) in a crossover design.[6] Both preparations contained 30 μg of ethinyl estradiol.

Multiple-dose studies. Unlike most other drugs,

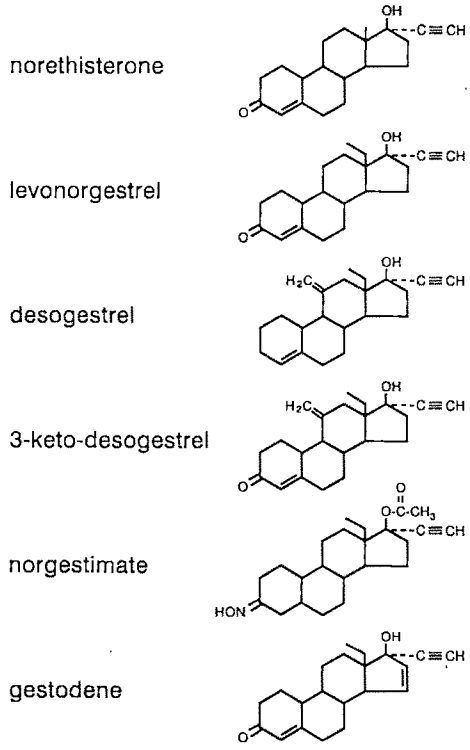

Fig. 1. Chemical structures of progestins used in oral contraception.

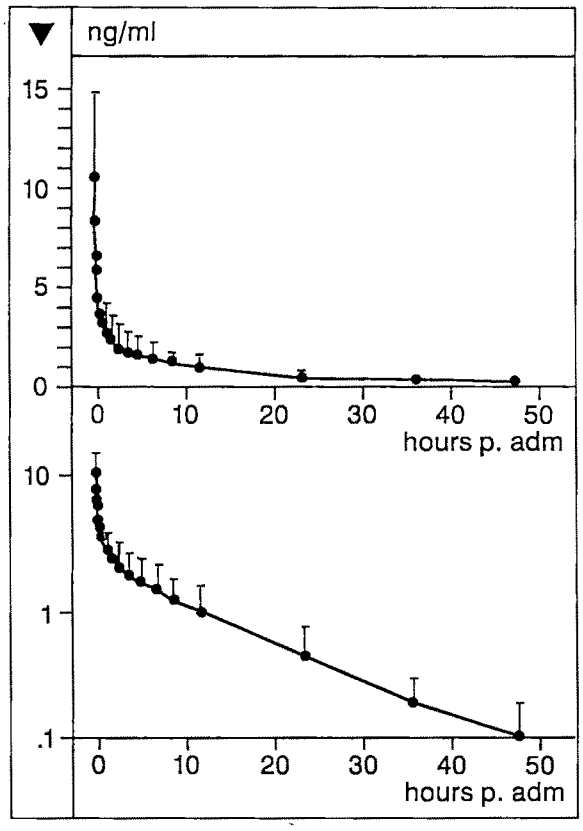

Fig. 2. Plasma gestodene levels after intravenous administration of 75 μg of gestodene to six women (mean ± SD). *Upper figure:* Linear scale; *lower figure:* semilog scale. (From Taüber U, Tack JW, Matthes H. Contraception 1989;40:461-79, Reprinted with permission of Butterworth Publishers.)

plasma levels of 19-nortestosterone–type progestins during multiple dosing cannot be predicted from single-dose pharmacokinetics. This is due to the induction of sex hormone–binding globulin (SHBG) by the concomitant administration of ethinyl estradiol and specific binding of 19-nortestosterone–type progestins to SHBG.[1]

In three studies the plasma or serum levels of gestodene and also those of SHBG and cortisol-binding globulin have been followed over longer time spans.[7-9] In the last study the protein-binding characteristics of progestins were also analyzed, comparing gestodene with 3-ketodesogestrel.[9]

Assays. Total concentrations of gestodene and ethinyl estradiol in plasma or serum were determined after diethyl ether extraction by specific radioimmunoassays developed in the research laboratories of Schering AG.[5, 10] SHBG, cortisol-binding globulin, and cortisol levels were measured with commercial kits.[8]

Free fraction, albumin, and SHBG-bound proportions of sex steroids were determined after spiking of ex vivo samples with ^{3}H-gestodene, ^{3}H-ketodesogestrel, or ^{3}H–ethinyl estradiol (specific radioactivity >1.5 TBq/mmol) by means of an ultrafiltration method similar to that described by Kuhnz et al.[9] and Hammond et al.[11]

Results

Gestodene: Single-dosing. Distribution and elimination processes can be studied undisturbed by absorption phenomena only after intravenous administration. After single intravenous administration of 75 μg as solution, the concentration of gestodene in the plasma declined in three different phases for which half-lives of 10 ± 7 minutes, 1.5 ± 1.4 hours, and 10 ± 2.3 hours have been calculated (Fig. 2). First and second disposition half-lives mainly reflect distribution processes; the terminal half-life reflects the elimination of the drug from the plasma. Gestodene is highly bound to plasma proteins. The apparent volume of distribution of the central compartment (V_C) was determined as 0.15 ± 0.06 L/kg. The volume of distribution during the terminal phase (V_Z) was 0.66 ± 0.43 L/kg.[5]

Gestodene is almost entirely metabolized before it leaves the body. Less than 1% of the dose has been found unchanged in the urine. As with many other steroids, gestodene is metabolized into a large number of metabolites. Biotransformation pathways comprise reduction processes at the 3-keto group as well as at the Δ^4-double bond, hydroxylation at various points of the molecule (including C1, C6, and C11), and conjugation (Fig. 3). By cochromatography of a metabolite isolated from dog urine, it was estimated that <4% of the dose was excreted in the form of a deethinylated,

D-ring homoannulated metabolite. The metabolites of gestodene were mainly excreted with the urine with a half-life of approximately 24 hours. Total plasma clearance of gestodene, which represents metabolic clearance, was 0.80 ± 0.53 ml/min/kg (Table III).

After oral administration, gestodene is rapidly absorbed into the systemic circulation. Maximum concentrations are reached after 30 minutes to 3 hours. No absorption problems have been observed after dosage of the tablet formulation. One-hundred percent of the dose reaches the systemic circulation unchanged, as seen from a comparison of areas under the plasma concentration-time curve after oral and intravenous administration; that is, gestodene undergoes no mentionable first-pass metabolization during the absorption process. Plasma concentration-time profiles for gestodene after oral and intravenous administrations are stikingly similar and are essentially superimposable after the absorption process is finished (i.e., 2 to 3 hours after dosing).

The pharmacokinetics of gestodene are dose linear over the whole therapeutic range and cover all dosage forms of both monophasic and triphasic preparations; that is, underlying pharmacokinetic processes obey first-order mechanisms. Plasma levels of gestodene and areas under the plasma level curves increased linearly with the dose, whereas all other pharmacokinetic parameters, such as time of maximum concentration,

half-lives, volumes of distribution, clearance rate, and bioavailability, were independent of the dose (Fig. 4 and Table IV).[5]

Usually there is only one binding protein for drugs; that is, albumin, which is available in high concentrations in plasma or serum. Certain basic drugs are bound to the α_1-acidic glycoprotein. In 19-nortestosterone progestins but not in C21-progestins, another binding protein, the so-called SHBG that physiologically binds testosterone and estradiol, plays an important role.

Intake of ethinyl-containing oral contraceptives can lead to a gradual increase in SHBG concentration in the plasma. The extent of the SHBG increase depends on the estrogen-progestogen balance of a preparation, that is, on the dose of ethinyl estradiol and on the dose and nature of the progestin. Table V shows the nonprotein-bound fraction and the albumin- and SHBG-bound fraction of gestodene in women with basal (77 ± 28 nmol/L) and induced (186 ± 57 nmol/L) SHBG levels. A 2.4-fold increase in SHBG levels led to a decrease in the free fraction of gestodene, from 1.9% ± 0.3% to 0.6% ± 0.1%. This change in the

nonprotein-bound fraction is obviously caused by a redistribution of gestodene in the human body. At low SHBG levels, almost equal proportions were bound to albumin and SHBG, whereas in the induced SHBG state, the proportion bound to SHBG was more than threefold higher than the proportion bound to albumin.

A competition experiment with the serum of pregnant women confirms the results of the ex vivo–binding studies. The serum of pregnant women containing high levels of SHBG was loaded with ^{3}H-dihydrotestosterone as ligand. The replacement of ^{3}H-radioactivity by various progestins was measured as a function of their concentrations. Relative-binding affinity decreased in the order of gestodene > levonorgestrel > 3-ketodesogestrel (Muhn-Seipoldy HP. Unpublished results) (Fig. 5).

Gestodene: Multiple dosing. Oral contraceptives are taken long term in a regimen of a once daily for 3 weeks followed by a pill-free interval of 1 week. Because of the periodic increase of SHBG over each cycle and the specific binding of gestodene to this protein, serum levels of gestodene cannot be predicted by computer simulation from single-dose pharmacokinetic parameters.

Fig. 6 shows the time course of total gestodene trough levels and SHBG levels in a subject receiving the monophasic preparation over one cycle. Both compounds increased in the plasma up to days 8 to 10, at which time steady state was reached. During the intake-free intervals, gestodene but not SHBG achieved pretreatment values, owing to their different half-lives of 18 hours and 10 to 14 days, respectively.[4]

In Fig. 7 average area under the curve values of total and free gestodene serum level curves determined in 11 women on days 1, 10, and 21 in cycles 1, 3, 6, and 12 are presented.[12] The free levels are in a dynamic equilibrium with concentrations at the target tissues. The periodic increases in total gestodene concentrations and area under the curve values during each cycle are higher than the accumulation determined by the half-life and the dosing interval. Increases observed can be easily explained by the periodic increase in SHBG up to 300% above pretreatment levels and the high-specific binding of gestodene to this binding protein.

Ethinyl estradiol. Fig. 8 shows mean time course of

AUC, Area under the curve.

*Measured per average on day 14 of cycle after an average intake period of 11 (Femovan) and 38 (Marvelon) months.

†AUC calculations based on sampling points, 0, 0.5, 1, 1.5, 2, 3, 4, 6, 8, 12, and 24 hours.

‡AUC calculations based on sampling points 0, 0.5, 1, 2, 3, 4, and 24 hours.

ethinyl estradiol levels in a group of 18 women who received Femovan and Marvelon in a randomized crossover design with a washout period of 1 week between both administrations. Area under the curve (0 to 4 hours) values for both preparations were equal and were also equal to those determined after long-term use of both preparations. Area under the curve (0 to 24 hours) values for long-term use (per average day 14 of cycle in both preparations) were approximately 25% to 30% higher than those after single administration (Table VI). This increase is less than that observed by Kaufmann et al.[13] in ethinyl estradiol trough levels of women using oral contraceptives containing levonorgestrel and 30 or 50 μg of ethinyl estradiol, but is in agreement with the accumulation of ethinyl estradiol that was predictable from plasma half-lives of 6 to 8 hours found by most authors for ethinyl estradiol.[14] Likewise, no difference between Femovan and Marvelon was seen in SHBG, cortisol-binding globulin, or cortisol levels.[7, 8]

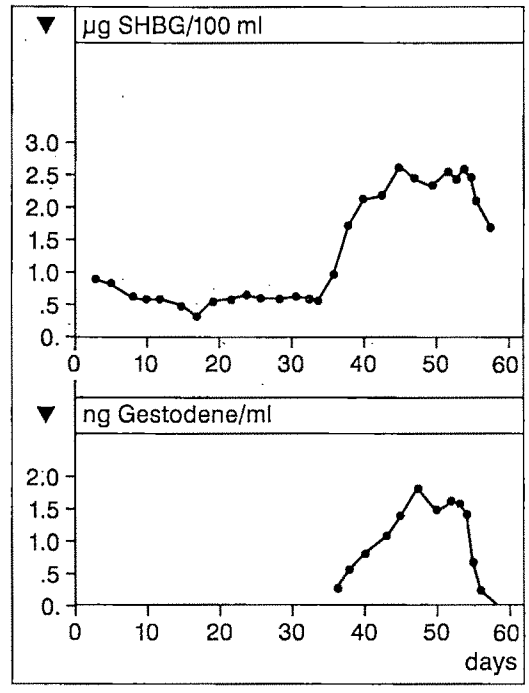

Fig. 6. Plasma levels of SHBG and gestodene as determined for a control cycle and a 21-day treatment cycle (75 μg of gestodene and 30 μg of ethinyl estradiol) in one test subject. (From Düsterberg B, Tack JW, Krause W, Hümpel M. In: Elstein M, ed. Gestodene: development of a new gestoden low-dose contraceptive. Carnforth, England: Parthenon Publishing, 1987:35-44.)

Comment

The monophasic oral contraceptive combining gestodene and ethinyl estradiol provides complete and rapid absorption and bioavailability of gestodene with dose-linear pharmacokinetics. Plasma levels of ethinyl estradiol are no different from those observed with another preparation containing the same amount of ethinyl estradiol.

Periodic increases in the serum levels of gestodene are seen from day 1 through day 8 during each cycle. Gestodene is highly bound to plasma proteins. Slightly more than three fourths of total serum gestodene is bound to SHBG and nearly all the balance to albumin.

Active young female in late teens looking for lasting relationship with OC. Concerned about side effects of acne and bloating.
Career - oriented woman in mid-20s wants to find right OC. Wishes to avoid side effects such as weight gain, headache, and depression. Open to raising a family — but later.

A personalized approach to oral contraceptives.

Because Tri-Norinyl is uniquely phased for all phases of a woman's reproductive life, it's ideal for a wide range of patient types:

Older, nonsmoking patients restarting contraception, because Tri-Norinyl is the only multiphasic with low-impact norethindrone that *lowers* progestin in late cycle to minimize overall hormonal and metabolic impact.

Career-oriented patients delaying childbearing, because reduced progestin helps minimize side effects that can disrupt daily life, such as weight gain, headache, and depression.

Younger patients just starting contraception, because low-impact norethindrone lowers the risk of acne and bloating, and is increased at mid-cycle, to provide enhanced endometrial support when breakthrough bleeding is most likely to occur.

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL®

Uniquely phased for all phases of a woman's reproductive life

Committed to the OB/GYN and women's healthcare

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL®

Uniquely phased for all phases of a woman's reproductive life

ORAL CONTRACEPTIVE AGENTS: BRIEF SUMMARY

DESCRIPTION

TRI-NORINYL 21-DAY Tablets provide an oral contraceptive regimen of 7 blue tablets followed by 9 yellow-green tablets and 5 more blue tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg and each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg.

TRI-NORINYL 28-DAY Tablets provide a continuous oral contraceptive regimen of 7 blue tablets, 9 yellow-green tablets, 5 more blue tablets, and then 7 orange tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg, each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg, and each orange tablet contains inert ingredients.

INDICATIONS AND USAGE

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use these products as a method of contraception.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions: Thrombophlebitis or thromboembolic disorders • A past history of deep vein thrombophlebitis or thromboembolic disorders • Cerebral vascular or coronary artery disease • Known or suspected carcinoma of the breast • Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia • Undiagnosed abnormal genital bleeding • Cholestatic jaundice of pregnancy or jaundice with prior pill use • Hepatic adenomas, carcinomas or benign liver tumors • Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long-term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users, cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS**, section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral contraceptive users is based on data gathered in the 1970's—but not reported in the U.S. until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral contraceptive use to women who do not have the various risk factors listed in this labeling.

Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular disease risks may be increased with oral contraceptive use after age 40 in healthy non-smoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception.

Therefore, the Committee recommended that the benefits of oral contraceptive use by healthy non-smoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (> 8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T4 concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING.**

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section): Thrombophlebitis • Arterial thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemorrhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenomas, carcinomas or benign liver tumors

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis • Retinal thrombosis

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spotting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminution in lactation when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepening) • Intolerance to contact lenses

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome • Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness • Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: • Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea

Effects related to inhibition of ovulation: • Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use: • Decreased incidence of fibroadenomas and fibrocystic disease of the breast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

Human oocyte and preembryo donation: An evolving method for the treatment of infertility 1421

Mark V. Sauer, MD, and Richard J. Paulson, MD

Los Angeles, California

This article reviews the evolution of the technology currently used in preembryo donation and discusses future roles for ovum donation in the assisted reproductive technologies.

Does obstetric ethics have any role in the obstetrician's response to the abortion controversy? 1425

Frank A. Chervenak, MD, and Laurence B. McCullough, PhD

New York, New York, and Houston, Texas

The obstetrician's response to the abortion controversy is ethically analyzed on the basis of responses to the question, "When is the fetus a patient?" and the distinction between professional and private conscience.

Clinical Articles

Interleukin-1β, human leukocyte antigen HLA-DRα, and transforming growth factor-β expression in endometrium, placenta, and placental membranes 1430

Scott Kauma, MD, Dennis Matt, PhD, Stephen Strom, PhD, David Eierman, PhD, and Thomas Turner, BS

Richmond, Virginia

Interleukin-1β, human leukocyte antigen HLA-DRα, and transforming growth factor-β are expressed at the maternal-fetal interface during pregnancy and may regulate the maternal immune response to the fetal semiallograft.

Prevalence and determinants of estrogen replacement therapy in elderly women 1438

Jane A. Cauley, DrPH, Steven R. Cummings, MD, Dennis M. Black, PhD, Stephen R. Mascioli, MD, and Dana G. Seeley, MS

Pittsburgh, Pennsylvania, San Francisco, California, and Minneapolis, Minnesota

Only a small proportion of elderly women in the United States use estrogen replacement therapy; selection factors for use of estrogen are evident and may introduce bias in studies of estrogen and disease.

Immunocytochemical distribution and localization of 15-hydroxyprostaglandin dehydrogenase in human fetal membranes, decidua, and placenta 1445

Paul Y. C. Cheung, BSc, John C. Walton, MD, Hsin-Hsiung Tai, PhD, Simon C. Riley, PhD, and John R. G. Challis, PhD, DSc

London, Ontario, Canada, and Lexington, Kentucky

At term, immunoreactive prostaglandin dehydrogenase is localized to trophoblast cells in the human chorion-decidua and to intermediate and syncytiotrophoblast cells in placenta, but the distribution of this immunoreactivity does not change with labor.

The effect of physical activity during pregnancy on preterm delivery and birth weight 1450

Mark A. Klebanoff, MD, MPH, Patricia H. Shiono, PhD, and J. Christopher Carey, MD

Bethesda, Maryland, Los Altos, California, and Oklahoma City, Oklahoma

Reported physical activity was minimally associated with either preterm delivery or gestational age–adjusted birth weight in a prospective cohort of 7101 women.

Prenatal diagnosis of laryngeal atresia 1456
William J. Watson, MD, John M. Thorp, Jr., MD, Richard C. Miller, MD, Nancy C. Chescheir, MD, Vern L. Katz, MD, and John W. Seeds, MD
Chapel Hill, North Carolina

Ultrasonographic findings in a fetus with laryngeal atresia included enlarged echogenic lungs, compressed heart, and hydrops with ascites and scalp edema.

Correlations between antepartum maternal metabolism and newborn behavior 1458
Thomas Rizzo, PhD, Norbert Freinkel, MD, Boyd E. Metzger, MD, Roger Hatcher, PhD, William J. Burns, PhD, and Peter Barglow, MD
Chicago, Illinois

Poorer antepartum maternal glucoregulation correlated with poorer ratings in three of four dimensions of neonatal neurobehavioral status in pregnancies complicated with diabetes mellitus.

Antenatal microbiologic and maternal risk factors associated with prematurity 1465
James A. McGregor, MDCM, Janice I. French, CNM, MS, Ruth Richter, CNM, MSN, Amalia Franco-Buff, MS, Anne Johnson, MS, Sharon Hillier, PhD, Franklyn N. Judson, MD, and James K. Todd, MD
Denver, Colorado, and Seattle, Washington

Presence of bacterial vaginosis, vaginal *Mycoplasma hominis,* and prior preterm birth was associated with preterm labor in a prospective study of 202 pregnant women.

The relationship between plasma estradiol and the increase in bone density in postmenopausal women after treatment with subcutaneous hormone implants 1474
J. Studd, M. Savvas, N. Waston, T. Garnett, I. Fogelman, and D. Cooper
London, England

A significant increase in bone density was seen in postmenopausal women receiving subcutaneous estradiol and testosterone that correlated with the serum estradiol level.

Fetal eye movement assessed with real-time ultrasonography: Are there rapid and slow eye movements? 1480
Naoki Horimoto, MD, Takashi Koyanagi, MD, Shoji Satoh, MD, Toshiyuki Yoshizato, MD, and Hitoo Nakano, MD
Fukuoka, Japan

Rapid and slow eye movements were evident during the eye movement period in the human fetus at 33 weeks' gestation and afterward.

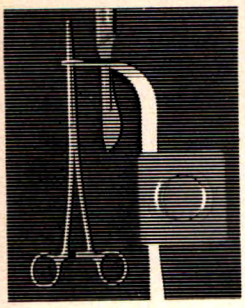
CEFOTAN® IM/IV

(cefotetan disodium)



In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli.*
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.
Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.
In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.
NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).
The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.
If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.
CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.
WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.
Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.
Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.
Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.
PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.
In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.
CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.
INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.
DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.
As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.
CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.
Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.
Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.
DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.
Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.
When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

$$\text{Females:} \quad 0.9 \times \text{value for males}$$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.
HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

Continuous or interrupted fascial closure: A prospective evaluation of No. 1 Maxon suture in 402 gynecologic procedures 1485
James W. Orr, Jr., MD, Pamela F. Orr, RN, Jeffrey M. Barrett, MD, John R. Ellington, Jr., MD, Ralph H. Jennings, Jr., MD, Keith B. Paredes, MD, Bruce Patsner, MD, and Dale L. Taylor, MD
Lakeland, Florida

There was no clinical or statistical difference in acute or long-term wound complications when continuous and interrupted abdominal fascial closures were compared.

Endometrioma of the liver 1490
Vittorio Rovati, MD, Edoardo Faleschini, MD, Paolo Vercellini, MD, Giovanni Nervetti, MD, Giorgio Tagliabue, MD, and Guido Benzi, MD
Milan, Italy

A patient with associated endometrioma of the liver and left ovary is described.

Antinuclear antibodies in sera of patients with recurrent pregnancy wastage 1493
Ling Xu, MD, Victoria Chang, BS, Ana Murphy, MD, John A. Rock, MD, Marian Damewood, MD, William Schlaff, MD, and Howard A. Zacur, MD, PhD
Baltimore, Maryland

Women who experience explained or unexplained repeated pregnancy losses have comparable rates of antinuclear antibody–positive sera exceeding those of pregnant and nonpregnant women.

Corpus luteum function in early pregnancies is primarily determined by the rate of change of human chorionic gonadotropin levels 1497
Paul G. Kratzer, MD, PhD, and Robert N. Taylor, MD, PhD
San Francisco, California

Human corpus luteum activity was correlated with the rate of change of human chorionic gonadotropin and did not appear to be correlated with any other serum factors.

Hemoperitoneum as a result of coital injury without associated vaginal injury 1503
Sterling W. McColgin, MD, Lisa M. Williams, MD, Timothy L. Sorrells, MD, and John C. Morrison, MD
Travis Air Force Base, California, and Jackson, Mississippi

Five cases of hemoperitoneum associated with coital injury but without associated vaginal injury are presented and discussed.

Postmortem chorionic villus sampling is a better method for cytogenetic evaluation of early fetal loss than culture of abortus material 1505
Mark Paul Johnson, MD, Arie Drugan, MD, Frederick C. Koppitch III, MS, Wendy R. Uhlmann, MS, and Mark I. Evans, MD
Detroit, Michigan

Postmortem chorionic villus sampling is a safe, rapid, and reliable technique for the karyotypic evaluation of early pregnancy loss.

THE PERMANENTE MEDICAL GROUP

NORTHERN CALIFORNIA

The Permanente Medical Group, the largest multispecialty group practice in the U.S., is undergoing explosive growth in its Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley. Our rapid increase in membership has created practice opportunities throughout the region for additional BC/BE Obstetricians and Gynecologists.

Our physician-managed group is part of the comprehensive Kaiser Permanente Medical Care Program. As a TPMG physician, you have access to the latest medical technology and resources, the support of colleagues in all subspecialties — and the opportunity to provide excellent health care without the burdens of managing a practice.

Join us in one of these facilities:

QUALITY

STABILITY

LEADERSHIP

GROWTH

SUPPORT

REWARDS

Santa Rosa — Opening new hospital featuring seven LDR's. Ten OB/GYN physicians and five nurse practitioners. Specialties include infertility, colposcopy, laser surgery and hysteroscopy. Call required once every nine nights. In Northern California's wine country, one hour north of San Francisco.

Santa Clara/Milpitas/Sunnyvale — 28 member department includes 3 perinatologists, GYN oncologist and reproductive endocrinologist. Ongoing clinical research. Our academic-oriented facility has an independent fully-accredited OB/GYN residency and serves as a core rotation for Stanford Medical Students. Academic appointments possible.

San Jose/Gilroy — Our 18 OB/GYN physicians average 3,000 deliveries per year and offer a full range of services including infertility, dysplasia and gyn-urology. On call approximately three nights per month. In-house Level II nursery; prenatal service shared with our nearby Santa Clara medical center. Satellite office in Gilroy. Located south of San Francisco and about one hour from the Monterey coast. The surrounding hills create a pleasant environment in which to live and work.

Hayward/Fremont — Full range of OB/GYN services with Level III L&D/ICN, 3000 deliveries yearly. Full time staff includes perinatologist and four neonatologists. Medical center and associated medical office located on east shore of San Francisco Bay with easy access to entire Bay Area.

Walnut Creek — Department of 15 physicians, a perinatologist and seven nurse practitioners. Two physicians on call daily. Teaching responsibilities for third year residents affiliated with the University of California at San Francisco. Clinical appointments at UCSF also available. Expansion plans include a large ICN, and within five years, a completely new hospital.

Martinez/Antioch — Southern California climate, Northern California charm, Bay Area location. Primarily in/outpatient GYN, outpatient OB. Seven physicians and four nurse practitioners in office and hospital practice. Deliver at the Walnut Creek Medical Center. High-risk pregnancy clinic at Martinez. Labor room call once or twice a month.

Vallejo/Fairfield/Napa — Seventeen physicians and four nurse practitioners at these facilities. Approximately 2,900 deliveries performed each year at the Vallejo medical center. Usual call is every eighth night. Affiliated with David Grant Medical Center residency program at Travis Air Force Base. Our area offers diverse lifestyle options, with both recreational and cultural attractions nearby.

San Rafael/Petaluma — OB/GYN services are available at both the San Rafael Medical Center and the new Petaluma medical offices, which opened in January of 1989.

South Sacramento — Eight physicians and four nurse practitioners serve 104,000 members in fast-growing Central Valley area. Planning new family-oriented L&D facilities.

KAISER PERMANENTE
Good People. Good Medicine.

TPMG offers many benefits: scheduled time off with cross-coverage provided by your colleagues, continuing education, malpractice insurance, a substantial retirement program and special arrangements for physicians transferring from established practice. For complete information, call or send CV to: The Permanente Medical Group, Inc., Richmond Prescott, M.D., Physician Recruitment Services, Dept. AJOG-8346, 1814 Franklin, 4th Floor, Oakland, CA 94612. (800) 777-4912. EOE

Detection of congenital toxoplasmosis by chorionic villus sampling and early amniocentesis 1511
Walter Foulon, MD, Anne Naessens, MD, Luc de Catte, MD, and Jean-Jacques Amy, MD
Brussels, Belgium

A case of early and rapid prenatal diagnosis of congenital toxoplasmosis by chorionic villus sampling and amniocentesis is described.

The "stuck twin" phenomenon: Ultrasonographic findings, pregnancy outcome, and management with serial amniocenteses 1513
Barry S. Mahony, MD, Charles N. Petty, MD, David A. Nyberg, MD, David A. Luthy, MD, Durlin E. Hickok, MD, and Jack H. Hirsch, MD
Seattle, Washington

Serial amniocenteses may significantly improve the survival rate of twin gestations affected by the "stuck twin" phenomenon but may be associated with complications among survivors.

Twin-twin transfusion syndrome 1522
Michael A. Urig, MD, William H. Clewell, MD, and John P. Elliott, MD
Phoenix, Arizona

Twin-twin transfusion syndrome associated with acute polyhydramnios in one sac and oligohydramnios in the other is associated with nearly 100% mortality for both fetuses; aggressive amniocentesis appears to offer considerable hope for improved outcome.

Pregnancy in a patient with treated Wilson's disease: A case report 1527
Patrick Dupont, MD, Olivier Irion, MD, and François Béguin, MD
Geneva, Switzerland

Evaluation of the patient's condition before conception and adequate chelating treatment throughout gestation should permit a successful pregnancy in a patient with Wilson's disease.

Nature of gonadotropin-releasing hormone self-priming of luteinizing hormone secretion during the normal menstrual cycle 1529
Michael J. Sollenberger, MD, Elisabeth C. Carlsen, MD, Robert A. Booth, Jr., MS, Michael L. Johnson, PhD, Johannes D. Veldhuis, MD, and William S. Evans, MD
Charlottesville, Virginia

Gonadotropin-releasing hormone induces self-priming of luteinizing hormone release by amplifying the mass and rate of luteinizing hormone secretion, both of which are predicted by serum estradiol levels.

The perinatal impact of cocaine, amphetamine and opiate use detected by universal intrapartum screening 1535
Katherine M. Gillogley, MD, Arthur T. Evans, MD, Robin L. Hansen, MD, Steven J. Samuels, PhD, and K.K. Batra, PhD
Sacramento, California

In a universally screened obstetric population, 299 women were identified as using cocaine, amphetamines, or opiates; confounding demographic factors and perinatal outcome are analyzed.

Contents continued from page 11A

Prenatal diagnosis of fetal intracranial calcifications 1543
Yasutsugu Koga, MD, Masahiko Mizumoto, MD, Yoshinori Matsumoto, MD, Tetsuo Hattori, MD, Shinichi Tanaka, MD, Toshinobu Tanaka, MD, and Seiichiro Fujimoto, MD
Sapporo, Japan

Fetal intracranial calcifications in a case of intrauterine cytomegalovirus infection were clearly visible by cranial computed tomography and magnetic resonance imaging of the fetus.

Inhibition of aromatase activity by 8-bromo-cyclic adenosine monophosphate in cultured first-trimester human trophoblast 1546
Marie R. Rodway, MSc, Basil Ho Yuen, MB, and Peter C. K. Leung, PhD
Vancouver, British Columbia, Canada

Production of estradiol from androstenedione and testosterone in cultured first-trimester human trophoblast was decreased by treatment with 2 mmol/L 8-bromo-cyclic adenosine monophosphate.

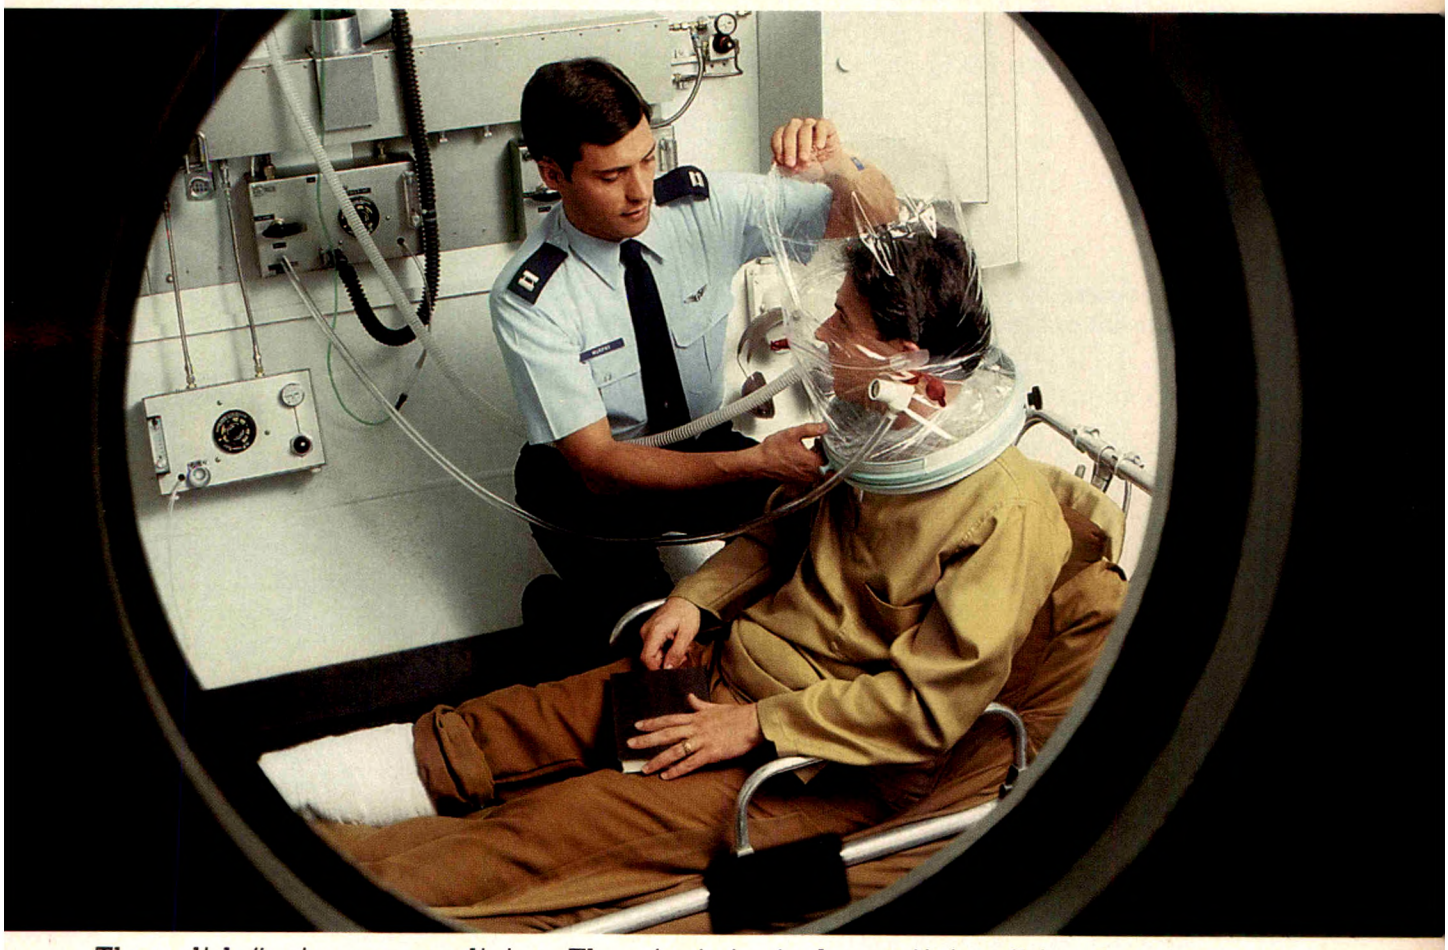
A reappraisal of the need for autologous blood donation in the obstetric patient 1551
Robert L. Andres, MD, Kathleen M. Piacquadio, MD, and Robert Resnik, MD
San Diego, California

Autologous donation of blood by the obstetric patient may not be beneficial or cost effective.

The Maylard incision in gynecologic surgery 1554
B. Frederick Helmkamp, MD, and Hans-B. Krebs, MD
Falls Church, Virginia

A prospective study of the transverse muscle-splitting Maylard incision used in 175 gynecologic patients is presented, and the technique is described in detail.

Ultrasonographic diagnosis of a large placental intervillous thrombosis associated with elevated maternal serum α-fetoprotein level 1558
Eric Jauniaux, MD, Donald Gibb, MD, Gonzalo Moscoso, MD, and Stuart Campbell, FRCOG
London, England



The ultrasonographic features of a developing placental intervillous thrombosis associated with elevated maternal serum α-fetoprotein levels are described.

Direct ultrasonographic measurement of fetal lung length in normal pregnancies and pregnancies complicated by prolonged rupture of membranes 1560
Alistair B. Roberts, MD, and Jennifer M. Mitchell, DMU
Auckland, New Zealand

Ultrasonographic measurements of fetal lung length were found to be a good predictor of pulmonary hypoplasia in patients wth prolonged rupture of membranes.

LAST YEAR, 43 DOCTORS GAVE UP PRIVATE PRACTICE FOR A CHALLENGING NEW CAREER.

They didn't give up medicine. They just started practicing it in a more exhilarating environment.

An environment that affords them many tangible benefits. Like a diverse practice, unlimited access to medical specialities, and financial security. Plus a lot of intangibles. Like a comfortable lifestyle, an opportunity for worldwide experiences and the respect that goes along with being an Air Force officer.

Of course, to enter an environment this rewarding, they did have to give up a few things. Like rent, equipment expenses, malpractice insurance, payrolls and utility bills.

Now, you may be intrigued by such a unique opportunity. But like any good medical professional, you'd probably like a complete case history. So call 1-800-423-USAF. Or send your curriculum vitae to Colonel William E. Patterson, United States Air Force/RSH, Randolph Air Force Base, Texas 78150-5421.

AIM HIGH.

Color flow Doppler—A useful instrument in the diagnosis of vasa previa 1566
James A. Harding, MD, David F. Lewis, MD, Carol A. Major, MD, Michael Crade, MD, Jagdish Patel, MD, and Michael P. Nageotte, MD
Long Beach and Orange, California

Color flow Doppler imaging was used to correctly identify vasa previa.

Reliability of ultrasonographic formulary in the prediction of fetal weight and survival of very-low-birth-weight infants 1568
Marlin D. Mills, MD, Michael P. Nageotte, MD, John P. Elliott, MD, Michael Crade, MD, and Wendy Dorchester, MPH
Phoenix, Arizona, and Long Beach, California

Antenatal ultrasonographic estimate of fetal weight >750 gm and obstetric estimate of gestational age ≥25 weeks predicts improved survival of very-low-birth-weight infants.

Management of selected cystic adnexal masses in postmenopausal women by operative laparoscopy: A pilot study 1574
William H. Parker, MD, and Jonathan S. Berek, MD
Los Angeles, California

Twenty-five postmenopausal women with clinically nonsuspicious cystic adnexal masses were screened with ultrasonography and CA 125; all had benign lesions and most of these were resectable by operative laparoscopy.

Hyperadrenergic orthostatic intolerance as a result of postpartum blood loss 1578
Scott L. Mader, MD, Judith A. Mackall, MD, and Martin P. Emert, MD
Cleveland, Ohio

This report describes orthostatic tachycardia and hypotension caused by protracted postpartum vaginal bleeding that required combination therapy with volume expansion and reduction of sympathetic nervous system activity.

Cervicovaginal microflora and pregnancy outcome: Results of a double-blind, placebo-controlled trial of erythromycin treatment 1580
James A. McGregor, MDCM, Janice I. French, CNM, MS, Ruth Richter, CNM, MSN, Margo Vuchetich, BSN, Vaundeen Bachus, BSN, Kyung Seo, MD, Sharon Hillier, PhD, Franklyn N. Judson, MD, John McFee, MD, Judith Schoonmaker, PhD, and James K. Todd, MD
Denver, Colorado, and Seattle, Washington

A short, defined course of erythromycin was used to examine relationships of cervicovaginal microflora with pregnancy outcomes and preterm birth.

Vitamin E levels in premenstrual syndrome 1591
C. James Chuong, MD, MPH, Earl B. Dawson, PhD, and Edward R. Smith, PhD
Galveston, Texas

Vitamin E deficiency in patients with premenstrual syndrome was not demonstrated in our study.

Contents

Intrauterine *Listeria* infection: Prenatal diagnosis by biophysical assessment and amniocentesis 1596
Robert I. Liner, MD
San Francisco, California

Decreased fetal movement with maternal flulike illness should prompt amniocentesis; in the absence of contractions the cause could still be fetal sepsis as a result of *Listeria.*

Pregnancy outcomes among mothers infected with human immunodeficiency virus and uninfected control subjects 1598
Howard L. Minkoff, MD, Cassandra Henderson, MD, Hermann Mendez, MD, Mitchell H. Gail, MD, PhD, Susan Holman, RN, MS, Anne Willoughby, MD, James J. Goedett, MD, Arye Rubinstein, MD, Pamela Stratton, MD, Judith H. Walsh, and Sheldon H. Landesman, MD
Brooklyn and Bronx, New York, and Bethesda, Maryland

After controlling for confounding variables, we found that children born to 91 women who were human immunodeficiency virus seropositive did not have significantly different birth weights, gestational ages, head circumferences, or Apgar scores than those born to 126 women who were human immunodeficiency virus negative.

Screening for trisomy 21 with ultrasonographic determination of biparietal diameter/femur length ratio 1604
Gerald P. Marquette, MD, Marc Boucher, MD, Micheline Desrochers, RN, and Louis Dallaire, MD
Montreal, Quebec, Canada

Ultrasonographic determination of the biparietal diameter/femur length ratio is not a sensitive screening test for trisomy 21.

Direct analysis of uncultured cytotrophoblastic cells from second- and third-trimester placentas: An accurate and rapid method for detection of fetal chromosome abnormalities 1606
Lee P. Shulman, MD, Avirachan T. Tharapel, PhD, Carole M. Meyers, MD, Owen P. Phillips, MD, Joe Leigh Simpson, MD, and Sherman Elias, MD
Memphis, Tennessee

Direct analysis of cytotrophoblastic cells obtained from second- and third-trimester placentas is an accurate and rapid method for detecting fetal chromosome abnormalities.

Perinatal mortality in Victoria, Australia: Role of group B streptococcus 1609
John R. Fliegner, MD, and Suzanne M. Garland, MD
Parkville and Carlton, Australia

Group B β-hemolytic streptococcus is responsible for >30% of perinatal deaths caused by infection and 1.7% of overall perinatal deaths.

(Contents continued on page 16A)

Contents continued from page 15A

Longitudinal study of the renin-angiotensin-aldosterone system in hypertensive pregnant women: Deviations related to the development of superimposed preeclampsia 1612
Phyllis August, MD, Tomas Lenz, MD, Kathy L. Ales, MD, Maurice L. Druzin, MD, Terri G. Edersheim, MD, J. Milton Hutson, MD, Franco B. Müller, MD, John H. Laragh, MD, and Jean E. Sealey, DSc
New York, New York

The circulating renin-angiotensin-aldosterone system, sex steroids, and renal function were studied in 30 pregnancies of women with chronic hypertension and compared with 58 previously studied normotensive women followed up longitudinally throughout pregnancy.

A comparison of sperm antibody assays 1622
Josef Daru, MD, and Subbi Mathur, PhD
Charleston, South Carolina

Cytotoxicity, Immunobead-binding (immunoglobulin G), and immunofluorescence (immunoglobulin G) sperm antibody assays correlate with each other versus sperm from autoimmune infertile men.

Extensive vulvar and vaginal varicella necessitating abdominal delivery 1630
Cynthia K. Sites, MD, David M. Sherer, MD, David L. Gandell, MD, and James R. Woods, Jr., MD
Rochester, New York

A case is reported in which a patient exposed to chickenpox early in pregnancy received varicella-zoster immune globulin; extensive varicella that developed at term necessitated abdominal delivery.

The role of fetal membranes in regulating production, transport, and metabolism of prostaglandin E_2 during labor 1632
John A. McCoshen, PhD, Dennis R. Hoffman, PhD, Jeremy V. Kredentser, MD, Carolina Araneda, and John M. Johnston, PhD
Winnipeg, Manitoba, Canada, and Dallas, Texas

Increased amniotic prostaglandin E_2 production during labor is not followed by concentration increases on the maternal side of the decidua because of chorion-decidual metabolism of prostaglandin E_2 during transport.

Surgical staples in cesarean section: A randomized controlled trial 1641
Marc G. Villeneuve, MD, Samir Khalifé, MD, Sylvie Marcoux, MD, PhD, and Pierre Blanchet, MD
Sainte-Foy, Quebec, Canada

In a randomized study, the use of the Auto Suture Poly CS 57 disposable surgical stapler for cesarean section hysterotomy reduced subjective blood loss but had no beneficial effect on operating time, postoperative febrile morbidity, or hospital stay.

The associated anomalies that determine prognosis in congenital omphaloceles 1646
Marisa Tucci, MD, and Harry Bard, MD
Montreal, Quebec, Canada

Newborns with giant omphalocele without associated anomalies of the heart, central nervous system, or diaphragm have a good prognosis.

Contents

Current Development

Ultrasonographic assessment of placental abnormalities 1650
Eric Jauniaux, MD, and Stuart Campbell, FRCOG
London, England

The prenatal diagnosis of placental abnormalities by ultrasonography is reviewed, and their pathophysiology and potential clinical implications are discussed.

BASIC SCIENCE SECTION

Progesterone increases cardiovascular toxicity to cocaine in nonpregnant ewes 1659
Mark A. Plessinger, MS, and James R. Woods, Jr., MD
Rochester, New York

The hypertensive response to cocaine was increased in nonpregnant ewes given progesterone intramuscularly, suggesting that the hormonal environment of pregnancy increases toxicity to cocaine.

Preferential mitogenic activity for myoblast-like cells can be extracted from uterine leiomyoma tissues 1665
Michael Koutsilieris, MD, PhD, Josée Michaud, BSc, and Andreas Nikolis, BSc
Quebec, Quebec, Canada

Extracts of human leiomyoma tissues, in addition to growth substances capable of stimulating or inhibiting the growth of cells with the osteoblast, myoblast, and fibroblast phenotype, contained substance(s) with a preferential activity for myoblast-like cells.

Platelet activating factor enhances in vitro fertilization of rabbit oocytes 1670
William E. Roudebush, PhD, Brijinder S. Minhas, PhD, Deborah D. Ricker, MS, Thomas V. Palmer, BS, and Melvin G. Dodson, MD, PhD
Johnson City, Tennessee

Platelet activating factor treatment of rabbit spermatozoa significantly increases in vitro fertilization rates of cumulus-free oocytes.

Adhesion formation after ovarian wound repair in New Zealand white rabbits: A comparison of ovarian microsurgical closure with ovarian nonclosure 1674
Anne K. Wiskind, MD, Andrew A. Toledo, MD, A. Gatewood Dudley, MD, and Kathryn Zusmanis, BS
Atlanta, Georgia

Microsurgical closure of ovarian surgical defects in New Zealand white rabbits is more adhesiogenic than nonclosure of ovarian wounds.

Effects of danazol, gonadotropin-releasing hormone agonist, and a combination of danazol and gonadotropin-releasing hormone agonist on experimental endometriosis 1679
Masahiro Sakata, MD, Naoki Terakawa, MD, Takahiro Mizutani, MD, Osamu Tanizawa, MD, Keishi Matsumoto, MD, Nobuyuki Terada, MD, and Katsuichi Sudo, PhD
Osaka, Japan

A combination therapy with danazol and gonadotropin-releasing hormone agonist may be a potential modality in the treatment of advanced endometriosis.

Uterine artery estrogen receptors in the nonpregnant and pregnant guinea pig 1685
Joseph R. Leiberman, MD, Cor C. J. van Vroonhoven, Tech., Ilse Beckmann, PhD, Theo H. van der Kwast, MD, and Henk C. S. Wallenburg, MD, PhD
Beer Sheva, Israel, and Rotterdam, The Netherlands

Estrogen receptors were found in the nuclei of cells belonging to endothelial, muscle, and adventitia layers of the uterine artery wall in the guinea pig.

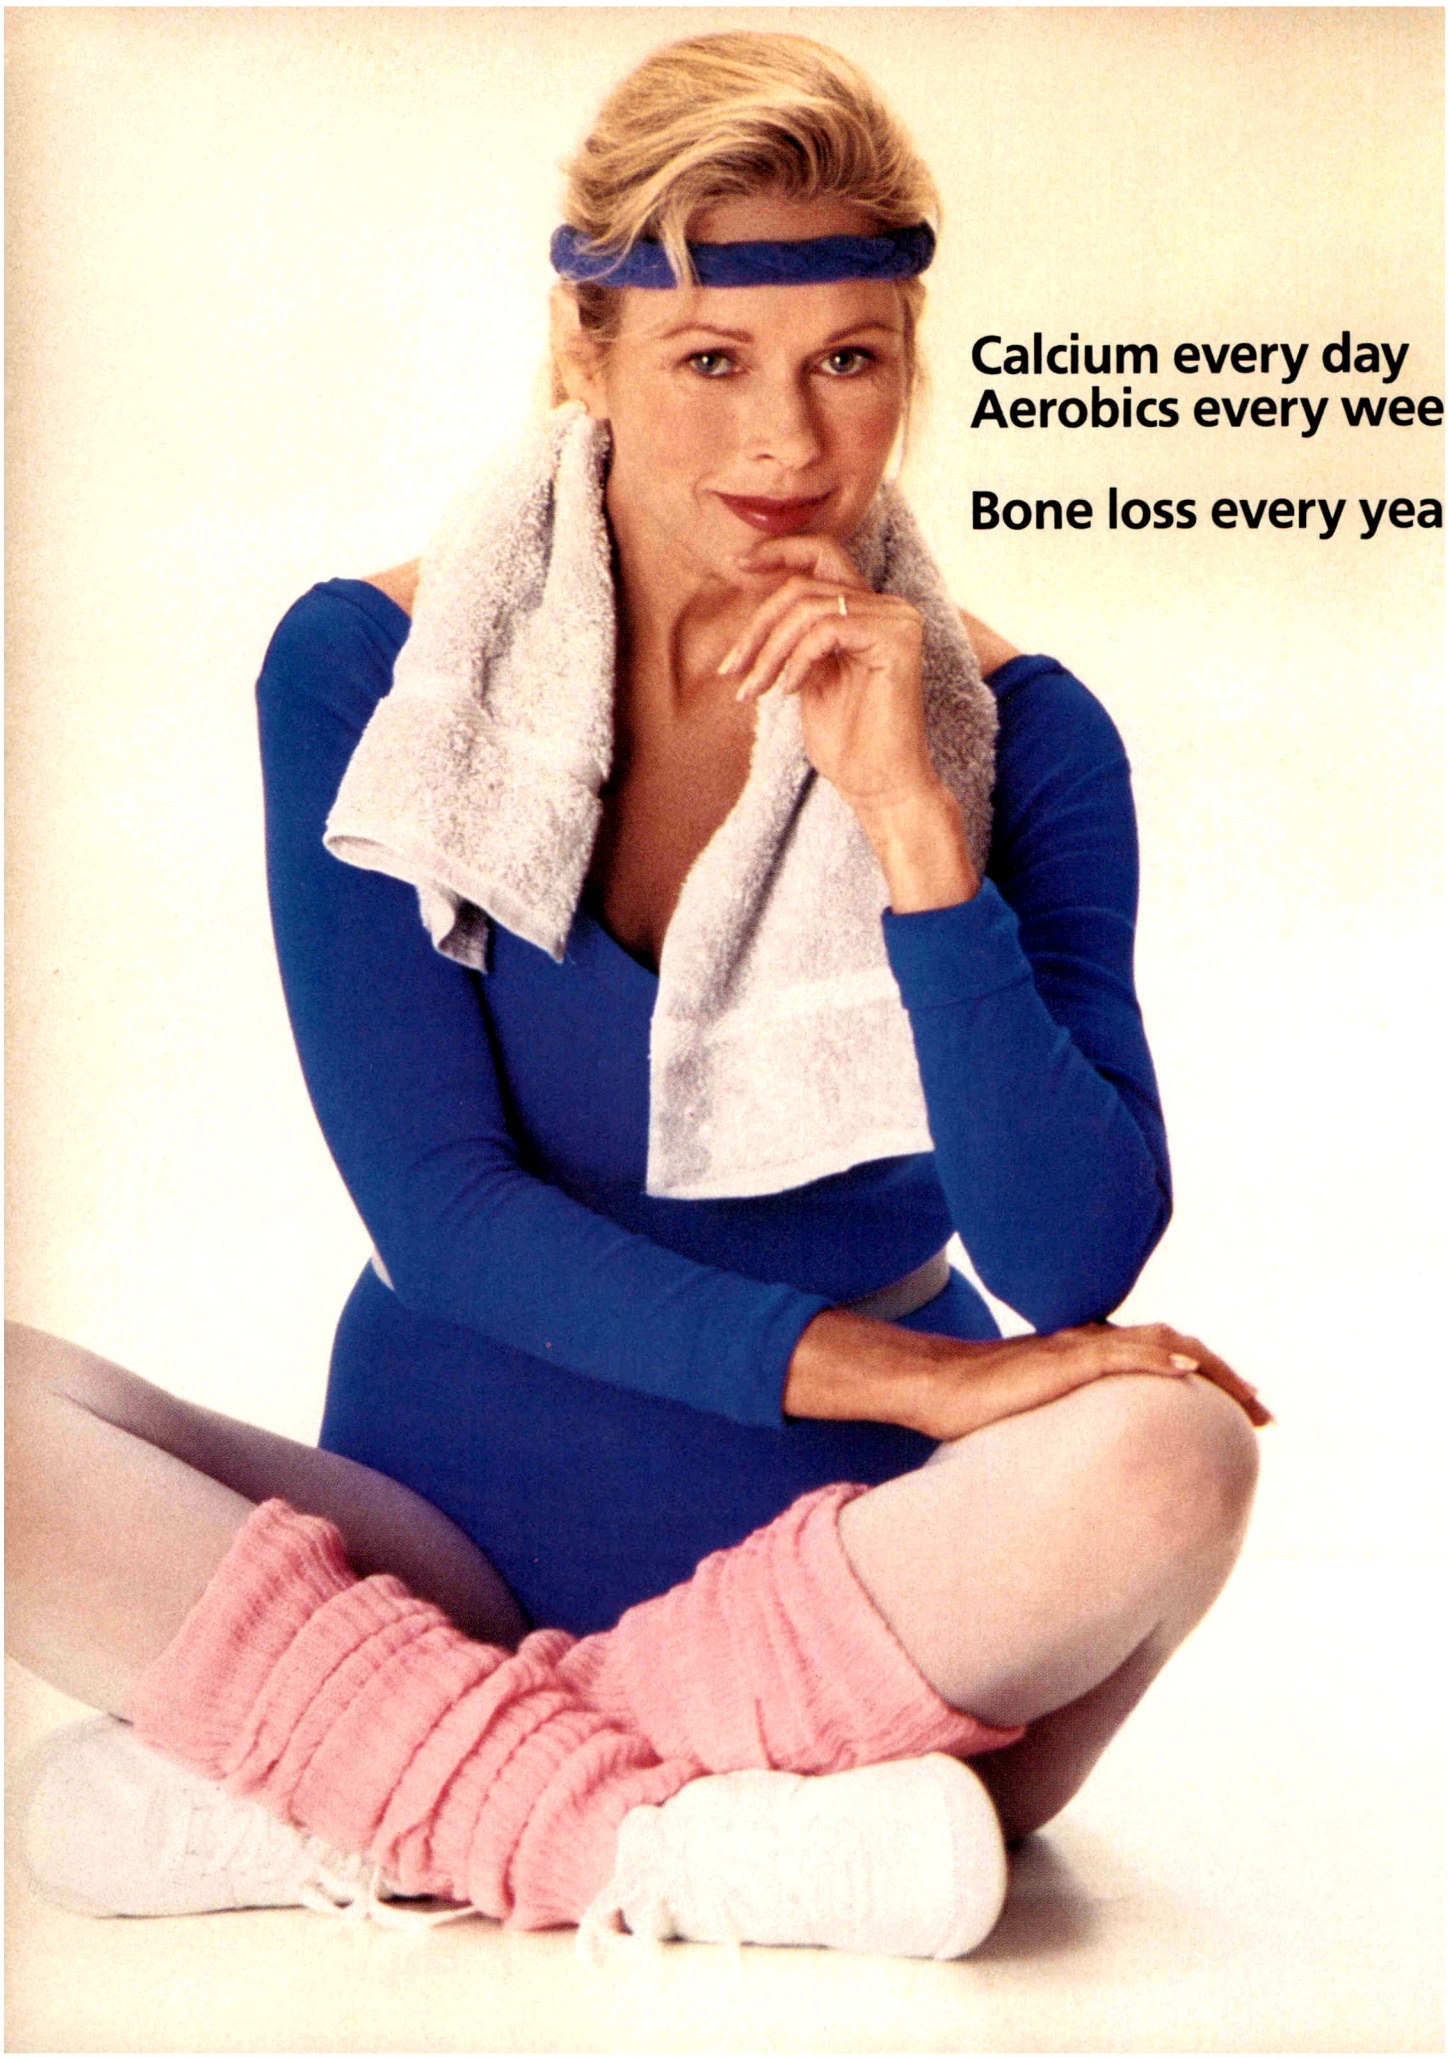
Index to advertisers on page 65A



Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318 USA; phone (314) 872-8370, ext. 7394. In the U.S., call toll-free: 1-800-325-4177, ext. 7394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

Authorization to photocopy items for internal or personal use, or the internal or personal use of specific clients, is granted by Mosby–Year Book, Inc., for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. The U.S. Government retains a nonexclusive, royalty-free license in and to any copyright on articles authored by government employees. 0002-9378/90 $00.00 + .10.

Calcium every day
Aerobics every wee
Bone loss every yea

She needs PREMARIN to help prevent further bone loss

Calcium[1] and exercise are not enough to prevent post-menopausal osteoporosis, since estrogen deficiency is the primary cause.[2] PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.[3]

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.[4]

PREMARIN®

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

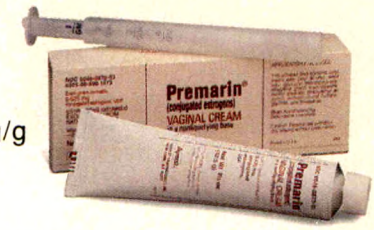
Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women. Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogen-dependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

See important information on adjacent page.

For moderate-to-severe vasomotor symptoms and for osteoporosis

PREMARIN®
(conjugated estrogens tablets)

0.3 mg 0.625 mg 0.9 mg 1.25 mg 2.5 mg



The appearance of these tablets is a trademark of Wyeth-Ayerst Laboratories.

For atrophic vaginitis

PREMARIN®
(conjugated estrogens)

Vaginal Cream

0.625 mg/g

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY. Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.
There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose.

Blood pressure should be monitored with estrogen use, especially if high doses are used.

Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risk, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding and mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associated with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progestin combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by T_4 levels determined by column or by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.
3. Impaired glucose tolerance.
4. Reduced response to metyrapone test.
5. Reduced serum folate concentration.

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See **CONTRAINDICATIONS** and Boxed Warning.

NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy; changes in vaginal bleeding pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterine fibromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of breasts; nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist when drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe vasomotor symptoms, atrophic vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.
2. *Given cyclically:* Hypoestrogenism. Osteoporosis.

Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 days followed by 10 day rest period. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the three Editors as follows:

1. **Dr. Brewer**—all manuscripts originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians.

2. **Dr. Zuspan**—manuscripts from the northeastern quadrant of the United States and from Japan, Israel, Italy, and England, manuscripts written for Clinical Opinion and Current Development, and Letters to the Editors. Dr. Zuspan is responsible for manuscripts from The Society of Perinatal Obstetricians. Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.

3. **Dr. Quilligan**—manuscripts from the north central states (including Ohio), states west of the Mississippi River, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.

Author's designation of reviewers. When authors submit their manuscripts, they may provide the names and addresses of three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances of the two reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the

Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher, and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, and business and home telephone numbers of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, and business and home telephone numbers of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3 type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize

Estimating length of manuscripts

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200-word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number are allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Fischermann E, Quilligan EJ, et al. Vaginal delivery following cesarean section—use of oxytocin augmentation and epidural anesthesia. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: James VHT, Folkerd EJ, Bonney RC, Beranek PA, Reed MJ. Factors influencing estrogen production and metabolism in postmenopausal women with endocrine cancer. In: van Herendael HB, Riphagen FE, Goessens L, van der Pas H, eds. The climacteric, an update. Lancaster, England: MTP Press, 1983:29.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Abstracts are not acceptable as numbered references.

Illustrations and tables. Illustrations and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice.

A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for *color illustrations* at a cost of $525 per page (one side).

For *color photographs* submit original transparencies and two sets of unmounted prints on glossy (smooth-surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The *top, first author's last name,* and *figure number* must be indicated on the front of each transparency and the back of each print. Consistency in size of illustrations within the article is strongly preferred.

For *black-and-white illustrations* submit three sets of 3×4 inch (minimum) to 5×7 inch (maximum) unmounted, glossy photographic prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black-and-white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted.

Do not use paper clips or mar the surface of prints in any way.

Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with): author(s) name(s), title of article, number, and top marked clearly.

Figures will be returned only on request by the author.

Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. *If a table or any part thereof has been taken from copyrighted material, a legend to the table must give full credit to the original source.* Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Legends to illustrations. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in

sequence after the references. Titles should be included in the legend, *not* on the print. Original magnifications should be provided. *If an illustration has been taken from copyrighted material, the legend must give full credit to the original source.*

Computer-generated illustrations. *Black-and-white illustrations* submitted must be legible and clearly printed in jet-black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend for the illustration should not appear on the print. On the back of each print the name of the first author and the figure number should be given and the top indicated. Original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color illustrations* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color illustrations. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Permissions. Direct quotations, tables, or illustrations that have appeared in copyrighted material must be accompanied by *written permission* for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words [excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"]. The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints

Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy photographic prints are submitted, properly numbered and labeled on the back of each print.
—Three sets of computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title
—Author(s) name(s) and highest academic degree(s)
—City(ies), state(s), and country other than U.S. in which the study was conducted are given
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated
—Acknowledgment of financial support is cited
—Name, address, and business and home telephone numbers of author to whom requests for reprints are to be sent
—Reprints will not be available. This has been stated on the title page
—Since the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, and business and home telephone numbers have been added
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a caption and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in sequence in the text.

Figures

—Are numbered in Arabic numerals and are cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Abstracts, personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted and the signed approval is enclosed.

Human oocyte and preembryo donation: An evolving method for the treatment of infertility

Mark V. Sauer, MD, and Richard J. Paulson, MD

Los Angeles, California

The utilization of oocyte and preembryo donation in the treatment of infertility has recently expanded. Since 1983, modifications in the retrieval of donated female gametes have enhanced both the safety and the efficacy of the procedure. Pregnancy rates in women receiving donated preembryos are remarkably high, with success occurring in 25% to 50% of transfer cycles. The technology used for preembryo donation continues to evolve, and the current and future role of ovum donation in the treatment of infertility is expanding. (Am J Obstet Gynecol 1990;163:1421-4.)

Key words: Preembryo donation, donor oocytes, uterine lavage, ovarian failure

Human oocyte and preembryo donation has become a viable medical alternative for treatment of infertility in women with ovarian failure. Approximately 0.3% of reproductive-aged women experience ovarian failure, which until recently represented an irrevocable loss of fertility.[1] However, with sex steroid hormone replacement and preembryo donation, functionally agonadal women now have an excellent chance of becoming pregnant.

The method used in human preembryo donation and its application for the treatment of infertility is relatively new. However, the utilization of this technique has become increasingly commonplace. Although initially directed at producing pregnancies in women with ovarian failure, recent success has also been reported after the transfer of donated preembryos to women with intact ovarian function but who otherwise have a poor fertility prognosis.[2] Summarized in this report are the evolution of preembryo donation in humans and the projected role of this method in infertility therapy.

Past developments

Since the late nineteenth century preembryo donation has been successfully performed in more than a dozen mammalian species. Most commonly, uterine lavage (endometrial washing) has been utilized to retrieve the free-floating conceptus before host implantation. This technique has been used in the breeding of exotic animals and has become increasingly popular in animal husbandry.[3] In the cattle industry the efficiency of this process is enhanced by superovulation of the donor cows, followed by their artificial insemination. In this manner multiple preembryos are obtained with uterine lavage. Preembryos that are retrieved are then individually transferred to multiple recipient animals, thus increasing the number of offspring generated per lavage procedure.[4]

Early attempts of ovum donation in humans utilized preembryo recovery techniques analogous to those used in animals. Between 1980 and 1987, clinical trials using uterine lavage of artifically inseminated fertile female donors resulted in the establishment of 13 clin-

ical pregnancies (Table I).[5,6] At that time uterine lavage represented the only nonsurgical alternative for procuring donated female gametes, since other assisted reproductive technologies, such as in vitro fertilization and gamete intrafallopian transfer, required the donor to undergo general anesthesia and laparoscopy. However, the natural fecundity of even the most fertile female donors limited the retrieval of viable preembryos to approximately 25% of cycles lavaged. Other aspects of this procedure lessened its clinical acceptability, as infection and retained pregnancies were observed in donors.[7]

Concomitant advances in the technology of human in vitro fertilization led to the use of this method for ovum donation. Initial reports of pregnancies in small series of functionally agonadal women using oocytes donated and fertilized in vitro appeared from 1984 through 1987.[8-10] These early attempts required the donor to undergo follicle aspiration surgically, usually by laparoscopy or minilaparotomy. Although the number of cases was small, results were encouraging, with most investigators reporting pregnancy rates of approximately 25% per embryo transfer attempt (Table II). However, the clinical applicability of this approach was limited by the difficulty of recruiting donors to undergo surgery. Furthermore, because of the inherent invasiveness of the follicle aspiration, the Ethics Committee of the American Fertility Society expressed concern that the risk of the procedure to the donor might outweigh the benefits of the procedure to the recipient couple.[11]

However, with time, technologic advances in ultrasonography led to the development of transvaginal ultrasonography-directed follicle aspiration. This simplification of the technique of in vitro fertilization has amounted to a technologic breakthrough for ovum donation. Transvaginal ultrasonography-directed follicle aspiration has proved to be a safe and effective means for retrieving oocytes. Women can now undergo oocyte aspiration without incurring the discomfort and risks of general anesthesia and surgery. Oocyte donors once again have a nonsurgical alternative.

Present status

The in vitro fertilization–embryo transfer registry of the Society of Assisted Reproductive Technology (SART) reported 17 clinics in calendar year 1987[12] and 26 clinics in calendar year 1988 that were performing in vitro fertilization–embryo transfer with donated oocytes.[13] In the 1988 series, 130 patients underwent 158 preembryo transfers. Fifty-one (32%) of the donor transfers produced a clinical pregnancy and 36 (23%) live deliveries resulted, including 12 sets of twins and one set of triplets. These numbers contrast with the 12% live-birth rate reported to SART in the same year for standard in vitro fertilization. There were no chromosomal abnormalities or congenital anomalies reported with this procedure.

A wide range of ethical issues surround donor payment and anonymity. While oocyte donation can be performed in either an anonymous or a directed fashion, most programs have maintained the anonymous approach and use supernumerary oocytes donated by couples undergoing in vitro fertilization. In other cases oocytes are donated by women agreeing to ovarian hyperstimulation before an operative procedure such as tubal ligation. In addition, sisters are often used as oocyte donors. In many cases couples prefer a sibling to an unrelated oocyte donor.[14] As the practice of oocyte donation has become a reality, the demand for donors has increased, resulting in a shortage of available donors and long waiting lists. Accordingly, several clinics have developed a registry of fertile women who agree to undergo ovarian hyperstimulation and follicle aspiration specifically for the purpose of donating all the gametes to the recipient. Again this practice may be performed anonymously.

At the University of Southern California a nonanonymous approach has been preferred.[15] Approximately half of our patients preselected a friend or sibling as a prospective donor before our evaluation. Couples with-

out a designated donor were matched nonanonymously with one of the several previously screened oocyte donors. This approach has occasionally allowed an individual oocyte donor known to produce large numbers of oocytes an opportunity to provide gametes to more than one recipient couple at a time.[16] A summary of the outcome of our initial 20 patients is listed in Table III.

Future considerations

Refinements of the present methods of preembryo donation will inevitably lead to simplified protocols for hormone replacement of the recipients. The endometria of functionally agonadal women can be successfully prepared by a variety of replacement protocols.[17] Most of these protocols use a combination of oral estradiol and intramuscular progesterone to establish a receptive endometrium. Our replacement regimen is depicted in Fig. 1. Its utilization at the University of Southern California has led to preembryo implantation rates that are threefold higher than those observed in our patients undergoing standard in vitro fertilization.[18] This increased implantation rate has led to higher pregnancy rates. Indeed, pregnancy rates reported with oocyte donation are among the highest

reported for any fertility-enhancing procedure. The unique combination of oocytes obtained from stimulated cycles in fertile women and the optimized endometrial environment in which these preembryos are placed make for these unprecedented results.

Recent reports of successful preembryo transfers to women made artifically agonadal after pituitary down regulation may establish an even greater applicability for donor oocytes.[2] Women with very poor fertility prognoses, such as those with failure of multiple attempts of in vitro fertilization, older women, or those who fail to respond to ovarian hyperstimulation, may ultimately benefit from endometrial preparation followed by oocyte donation.

Preliminary reports of pregnancies after unstimulated donor cycles or in ovaries incidentally removed from women at the time of surgery may further modify the approach to retrieving gametes.[19] Simplifying the procedural aspects of occyte donation should further reduce the present risks of ovarian hyperstimulation and aspiration.

In summary, pregnancy after oocyte and preembryo donation is now a reality and will become more commonplace as we approach the twenty-first century. Ironically, it appears that women who only a decade ago were considered hopelessly infertile may have a higher probability of conception after donor preembryo transfer than women with ovarian function undergoing standard in vitro fertilization.

Does obstetric ethics have any role in the obstetrician's response to the abortion controversy?

Frank A. Chervenak, MD, and Laurence B. McCullough, PhD
New York, New York, and Houston, Texas

We defend the view that the obstetrician's response to the abortion controversy cannot be based on accounts of the independent moral status of the fetus, because all such accounts are irresolvably disputable. That response, however, can be based on an account of the dependent moral status of the fetus. For such an account the central question is, "When is the fetus a patient?" Viable fetuses are patients. Nonviable third-trimester fetuses are not patients. Previable fetuses are patients solely as a function of the woman's autonomous decision to confer such status. The abortion of a viable fetus is, with few exceptions, never ethically justified, because it is a patient. The abortion of nonviable third-trimester fetuses (i.e., premature termination of pregnancy) is justified when the pregnant woman consents to it. Abortion of the previable fetus is justifiable when the pregnant woman consents to it. We distinguish between professional and private conscience. We identify the limits of the former and the legitimate role of the latter, especially in the area of religious beliefs. Finally, we address the implications of our view for residency training programs. The most important of these implications is that requiring all residents to perform abortions is ethically unjustifiable. (Am J Obstet Gynecol 1990;163:1425-9.)

Key words: Abortion, ethics, viability, residency education

Abortion ranks as one of the most divisive issues affecting contemporary American society. This divisiveness has the potential to extend to the obstetric profession because obstetricians counsel pregnant women and perform abortions. The voluminous literature on the ethics of abortion can be accurately described as a controversy for which closure on a common ground is impossible.[1] This is because of the markedly varied arguments about when, why, and by whom there might be ethical obligations owed to the fetus. As a consequence, it seems fair to ask, Does obstetric ethics have any role in the obstetrician's response to the abortion controversy? We believe that the answer is yes.

We understand obstetric ethics to be a subspecialty of the field of medical ethics. Medical ethics seeks to identify, on the basis of ethical principles, the ethical obligations of physicians to patients and to third parties to the patient-physician relationship, e.g., family members, hospitals, and public and private payers.[2, 3] Obstetric ethics seeks to identify the ethical obligations of the physician to the pregnant patient and to third parties to the patient-physician relationship. Of special interest is the issue of whether the physician has ethical obligations to the fetus. The history of medical ethics in the West began with Hippocrates.[4] Obstetric ethics is a part of this history and continues to be developed in the medical and philosophical literature. These discussions embrace the full range of ethical issues in obstetric practices, e.g., maternal-fetal conflict,[5] fetal diagnosis and treatment,[6] and abortion.[7]

Theological and philosophical responses

The first response of many persons to the abortion controversy is to try to establish theological or philosophical grounds for the independent moral status or lack of independent moral status of the fetus.[1, 8-10] Independent moral status would mean that the fetus in and of itself generated its own moral rights, which would have to be acknowledged and respected by everyone. The disabling problem with these responses is that they are so varied that no common ground has emerged and clinical application therefore has been impossible. Theological traditions are marked by deep disagreement, both intramurally and transmurally. In these matters, moreover, theological traditions have been unable to agree on a single perspective from which their disputes can be universally and authoritatively settled. Philosophical traditions have fared no better. Indeed, the voluminous philosophical literature on the ethics of abortion is markedly heterogeneous in its methods and results. Thus no single philosophical perspective can claim with legitimacy a primacy over any other. In 1973, the United States Supreme Court stated that philosophers and theologians have been unable to settle

the question of when human life begins, i.e., when the fetus has independent moral status. There has been no progress in the intervening years. Indeed there seems to be no common ground available.[7]

The implication for obstetricians of this lack of progress is that they should be deeply suspicious of any responses to the abortion controversy that assert an indisputable account about the independent moral status or lack of independent moral status of the fetus. Suspicion is justified because no such account can claim final intellectual or moral authority, given the necessarily disputable nature of all accounts of the independent moral status of the fetus.

The response of obstetric ethics

Obstetric ethics need not be paralyzed, however, because it does not need an account of the *independent* moral status of the fetus. This is because obstetric ethics asks a different question: When is the fetus a patient? This question is not about the independent moral status of the fetus. Instead it is a question about the *dependent* moral status of the fetus; that is, the moral status of the fetus is a function of whether the fetus always has the moral status of being a patient. It is not a function of some intrinsic property of the fetus, e.g., being a human being or being unique genetically. Obstetric ethics is competent to address the question of whether the fetus is always a patient.

We shall argue the following: When the fetus is not a patient, the response of obstetricians to the abortion controversy is clear. Pregnant women in consultation with their obstetricians should be permitted to make their own decisions for or against the moral status of the fetus and therefore about abortion. However, when the fetus is a patient, the response of obstetric ethics to the abortion controversy is that this freedom sometimes can be justifiably limited.

The distinctive advantage of obstetric ethics is that it can answer the question, "When is the fetus a patient?" on secular, philosophical grounds. Theological sectarian grounds cannot be invoked at this stage of inquiry because obstetric ethics is secular in character for two reasons. First, medicine as a social institution rests on secular intellectual foundations, the biomedical sciences, and a secular social sanction, licensure by the state. These are factual matters about the development of medicine in America. Second, as Engelhardt[11] has convincingly argued, (1) only a secular approach to medical ethics (of which obstetric ethics is a subspecialty) is adequate in a pluralistic society and (2) only philosophical methods are capable of articulating secular medical ethics in a pluralistic society. No theological approach can satisfy these two criteria.

Accounts of the independent moral status of the fetus are all based on claims about the *beginning* of fetal development, e.g., the "moment" of conception, or when twinning becomes impossible.[1,7] Because such accounts are all disputable, we anchor the continuum of ethical obligations to the fetus as a patient at the *end* of the continuum of human development. This is when independent moral status is not disputable, namely, when human beings become persons. Persons, in the philosophical (not legal) sense of the word, are rational, self-conscious entities that are ends in themselves. As such, they independently generate their own moral status in an unambiguous fashion. Such moral status also generates a person's rights and autonomy-based obligations to other persons. The biologically and socially sufficient conditions for becoming a person probably occur sometime during the latter half of, or shortly after, the neonatal period. Engelhardt's is perhaps the most thorough exposition of the implications of respect for persons for bioethics.[11] However, that persons generate their own independent moral status is a commonly accepted view in ethical theory.

Persons can become patients when they consent to do so. Pregnant women can become patients, therefore, when they consent to do so. However, one need not be a person to be a patient, as is plainly the case in neonatal medicine. This is because in medical ethics the physician can have beneficence-based obligations to human beings independently of whether they are persons. These obligations derive from the physician's role as a care giver and exist when it is reasonable to seek those human goods that medicine as a social institution is competent to achieve. These goods are the prevention of premature or unnecessary death and the prevention, cure, or amelioration of disease, injury, handicap, and unnecessary pain and suffering. Medicine's competence in this respect is a function of biomedical knowledge, clinical skills, and technical capacity.[3]

This line of reasoning applies to the question, "When is the fetus a patient?" in the following way. We understand the viability of a fetus to mean that it can survive delivery into the neonatal period and infancy, given appropriate biologic potential and the availability of biomedical interventions applied under the test of reasonableness, explained below. Viability thus has ethical significance because the viable fetus can become a person. Because viability involves both biologic potential and technologic capacity,[12] it is not an intrinsic property of the fetus but acquires its ethical significance in terms of the end point of the continuum of development into a person. Viability thus concerns the dependent moral status of the fetus. Moreover, viability will depend on the expertise of the medical community caring for a particular patient, on inherent variability of fetal maturation, and intrinsic uncertainties in the

determination of fetal gestational age. Hence it is not possible to establish a universal cutoff date for gestational age.

In medical ethics there is a beneficence-based obligation to intervene to prevent the death of a human being when it is possible and reasonable to do so. It is possible to do so when the human being in question is accessible to the physician for the purposes of applying clinical interventions. It is reasonable to do so when the attempt to intervene to prevent death does not involve overly burdensome risks of morbidity and mortality and is expected to result in net benefit.

The viability of the fetus means that it is accessible to the physician to become a patient, as a function of biomedical knowledge, clinical skills, and technologic capacity. Hence the physician has a beneficience-based obligation to intervene on behalf of the viable fetus, when it is reasonable to do so.[13]

There are two limits on this obligation. The first involves obligations owed to the pregnant woman.[13] The second involves the likelihood that the end point of the continuum of human development can be achieved; that is, the ethical implications of viability for the weight of the physician's and the pregnant woman's actual beneficence-based obligations to the fetus as a patient in particular cases are variable.

For some fetuses there is the high probability of diagnosis of an anomaly that will result with a very high probability in death as an outcome or survival with a very high probability of irreversible and severe cognitive developmental deficit. The beneficence-based obligations to intervene to prevent death for such fetuses are minimal. Minimal beneficence-based obligations are consistent with nonaggressive management of the pregnancy but not its termination, because direct killing violates minimal beneficence-based obligations to prevent the fetus' death because the woman has implicitly accepted such obligations by taking her pregnancy to viability.[14, 15]

Some fetuses have a prognosis of expected survival with no, or manageable, deficit of cognitive developmental capacity. Beneficence-based obligations to such fetuses are more than minimal. The test for overriding more than minimal beneficence-based obligations to the fetus is more demanding, especially when there is no maternal indication for not completing the pregnancy.[14] The justification for this view is that abortion does not prevent significant health risks to the pregnant woman and, by taking her pregnancy beyond viability, she has implicitly accepted an obligation to accept the normal risks of childbirth.[14] Thus there are circumstances when ethical obligations to the fetus as a patient can legitimately take precedence over the woman's intentions regarding her pregnancy.

This precedence is not absolute, however, because there may be reasonable exceptions. This is because pregnancy can very rarely pose unreasonable risks to the woman's life or health after fetal viability, risks that she is not ethically obligated to accept.[13] Hence she should be free to determine the disposition of her pregnancy when it poses significant risks of serious morbidity (e.g., stroke or blindness) or mortality to her. In such cases, if the woman were to decide to terminate the pregnancy, every effort should be made to minimize fetal morbidity and mortality, because the fetus remains a patient.

Some third-trimester fetuses are not viable because of lethal anomalies; they are therefore not patients, and no beneficence-based obligations are owed to them to intervene to prevent an inevitable death. This is the case when the diagnosis is certain and when there is certainty of death as the outcome of the anomaly diagnosed or, in cases of short-term survival, certainty of the absence of cognitive developmental capacity.[14, 16] Abortion of nonviable third-trimester fetuses (i.e., premature termination of pregnancy) is ethically permissible because there are no beneficence-based obligations to the fetus to prevent death on the part of the pregnant woman or physician.[14] Abortion of such fetuses is justified therefore when the pregnant woman consents to it.

No link can be established between the previable fetus and the end point of the continuum of human development via biomedical technologic capacity. This is simply what *previable* means. The only possible remaining link is the pregnant woman's choice about the disposition of her pregnancy. However, because that link is solely a function of her autonomous choice, the pregnant woman is under no ethical obligation to regard the previable fetus as a patient. The physician is therefore under no such obligation for the same reason. Thus, before viability, a pregnant woman is free to withhold, confer, or, having once conferred, withdraw the status of being a patient from the fetus. In other words, for secular obstetric ethics, the abortion controversy regarding previable fetuses is resolved for physicians by the autonomous decision of the woman regarding her pregnancy and the dependent moral status of the fetus as a patient.

There is in the literature on obstetric ethics an approach that holds that all of obstetric ethics is essentially a function of the pregnant woman's autonomy.[5, 17] On this approach, the distinction among viable, nonviable, and previable fetuses would be ethically insignificant. From this it would follow that the pregnant woman is free to withhold, confer, or, once having conferred, withdraw the status of being a patient from the fetus throughout pregnancy. With respect to previable and

nonviable fetuses, therefore, this approach to obstetric ethics and ours are in agreement on the response of obstetric ethics to the abortion controversy.

Some might object at this point that physicians have an obligation not to be an agent of harm to the previable fetus, independently of what a pregnant woman may choose; that is, the principle of *primum non nocere,* or nonmaleficence,[2] may be violated. We have two responses to this objection. First, *primum non nocere* is neither an absolute nor, indeed, a first principle of medical ethics in general or of obstetric ethics in particular. Instead, nonmaleficence is secondary to beneficence.[3] Second, even if *primum non nocere* were admitted as a primary consideration, it would only show that a physician should not harm a patient. It cannot be invoked to show that a biologic human being *is* a patient. The principle of beneficence cannot be used for this purpose either. Human beings become patients when they become accessible to physicians for the purposes of applying reasonable clinical interventions, which is not the case for previable or nonviable fetuses.

In summary, the response of obstetric ethics to the abortion controversy is the following. The abortion of previable fetuses, the central focus of the abortion controversy because virtually all abortions are performed before viability, involves no violation of the principles of secular obstetric ethics. Neither does the abortion of nonviable third-trimester fetuses, those with lethal anomalies. In both cases abortion does not involve violation of beneficence-based obligations. *Primum non nocere* is not violated either. In our view the abortion of viable fetuses to which minimal and more than minimal beneficence-based obligations are owed is not ethically justifiable, with the exceptions of the woman's decision to give precedence to her own life or to prevent significant health risks she is not obligated to accept.[14]

The abortion controversy and the distinction between professional and private conscience

Secular obstetric ethics generates the ethical obligations that an obstetrician as a health care professional has to patients. Secular obstetric ethics transcends differences of private morality because it binds the conduct of all obstetricians, as obstetricians. Obstetricians, however, also have private consciences, which are shaped by the private morality of each individual. Private morality is a function of such individual factors as personal experience, family upbringing, and religious tradition. In contrast to professional conscience, private conscience is variable because of the striking hetereogeneity of the sources of private conscience. Professional conscience governs the response to the abortion controversy of the obstetrician as a professional person bound by the obligations of a professional role. Private conscience cannot bear on the professional role but governs only the obstetrician's responses in his or her nonmedical roles of lay person and private citizen.

Professional conscience governs the obstetrician's obligations to his or her patient. Private conscience governs whether continuing to serve as an obstetrician to a particular patient obligates the physician to act in such a way as to produce intolerable burdens on his or her private moral convictions, values, and beliefs, including those of theological origin. Respect for the integrity of the private conscience of each individual obstetrician means that some human beings justifiably cannot become, or can cease for particular purposes to be, patients of a particular obstetrician. Thus, asserting respect for autonomy in the form of respect for the moral convictions, including religious convictions, of private conscience can sometimes be a legitimate ethical claim on the part of the obstetricians; that is, secular obstetric ethics underscores the legitimate role of religious belief in the formation of the private conscience of the obstetrician.

There are important limits on such a claim. Matters of private conscience do not govern the physician's response to the abortion controversy in obstetric ethics, only the morality of abortion in one's private moral life, i.e., in terms of one's response to one's roles other than that of being an obstetrician. Thus, on the basis of private conscience, one has no intellectual license to judge the morality of pregnant women who contemplate termination or continuation of their pregnancies or to judge adversely behavior of colleagues that is consistent with secular obstetric ethics as explained in the preceding section. Private conscience justifies only withdrawing from particular cases. When withdrawal is undertaken, professional conscience requires that the physician see to it that the pregnant woman's care is transferred in an orderly and safe manner to a colleague whose private conscience is not violated by the pregnant woman's decisions. No judgments about the morality of those decisions should be expressed to the pregnant woman, for whom the obstetrician acts exclusively in the role of physician, not a private person.

While private-conscience-based moral objections to a pregnant woman's decision should never be used to judge her, it does not follow that physicians as citizens have no freedom to add their private-conscience-based views on the morality of abortion to the ongoing public debates about abortion and public policy in our country. In doing so, however, when they invoke their professional mantle, their contribution must be governed in its moral content by secular obstetric ethics. Otherwise, obstetricians can join the political fray as interested lay persons or citizens, with no special or authoritative perspective *as obstetricians* on the abortion controversy. When obstetricians contribute as obstetricians to public debate on any topic, they are constrained by secular

medical ethics and its response to the question, "When is the fetus a patient?"

Implications for obstetric residency programs

The preceding has important implications for obstetric residency programs. We, like many others, have heard anecdotal reports that applicants to some residency programs sometimes learn, in one way or another, that all residents in those programs are required to perform abortions. We have inquired of the American College of Obstetricians and Gynecologists and the Council on Residency Education in Obstetrics and Gynecology for data on this subject, and we were told that no data have been collected.

Such an educational policy raises troubling ethical issues because it denies the integrity of private conscience and misinterprets secular obstetric ethics and its implications for professional conscience. As to the latter, all that obstetric ethics can show is that, when the fetus is not a patient, a pregnant woman possesses unrestricted freedom regarding the disposition of the pregnancy. Obstetric ethics does not show therefore that every obstetrician should carry out a pregnant woman's request for an abortion, because doing so may violate private conscience in some cases. Any educational program that requires all residents to perform abortions rests on a misunderstanding of the limits of professional conscience. That such a policy could unjustifiably violate private conscience is therefore plain.

This is different from the case that, on the basis of the religious traditions of the sponsoring institution, a residency program prohibits residents from being involved in performing abortions at that institution. This is because there is a well-established tradition in our society that religious institutions have the right to protect the integrity of their traditions so long as no harm befalls innocent, nonconsenting human beings. Because such a policy does not tell residents what to believe as a matter of private conscience, because such a policy is consistent with the limits of obstetric ethics, and when such a policy does not eliminate access to abortion in a community, it is ethically justified.

We are fully cognizant of the possibility of abuse of a policy that permits exceptions on the grounds of private conscience. The best remedy to prevent such abuse is (1) to require residents to document the basis of their objections to performing abortions in a rigorous way, analogous to the requirement imposed on citizens who seek conscientious objector status regarding military service, and (2) to define clearly the additional duties expected of residents in lieu of not performing abortions.

Comment

The abortion controversy in our country will not disappear. It seems to intensify with each new United States Supreme Court ruling and actions of state legislatures and governors on the subject. Obstetric ethics, precisely because of its secular character, equips physicians to respond to this ongoing controversy in the disciplined, reasoned fashion expected of members of a learned profession. By submitting to the intellectual discipline of secular obstetric ethics, physicians can act to prevent the divisiveness of the abortion controversy from extending to the medical profession.

Interleukin-1β, human leukocyte antigen HLA-DRα, and transforming growth factor-β expression in endometrium, placenta, and placental membranes

Scott Kauma, MD, Dennis Matt, PhD, Stephen Strom, PhD, David Eierman, PhD, and Thomas Turner, BS

Richmond, Virginia

Maternal immune recognition of the fetal semiallograft appears to be necessary and beneficial for fetal survival and growth. Interleukin-1β and human leukocyte antigen HLA-DR are important for foreign antigen recognition by the immune system, whereas transforming growth factor-β inhibits many of the immunostimulatory properties of interleukin-1β. In this study we found that first-trimester decidua and term placental membranes expressed significantly higher levels of interleukin-1β, interleukin-1β messenger ribonucleic acid, and human leukocyte antigen HLA-DRα messenger ribonucleic acid than proliferative and secretory endometrium. Fetal placenta had little, if any, interleukin-1β, interleukin-1β messenger ribonucleic acid, or human leukocyte antigen HLA-DRα messenger ribonucleic acid expression. All tissues found at the maternal-fetal interface, including first-trimester decidua, placenta, and placental membranes, contained transforming growth factor-β and expressed transforming growth factor-β, messenger ribonucleic acid. On the basis of these findings, we suggest that the increase in decidual interleukin-1β and human leukocyte antigen HLA-DRα during pregnancy may be involved in maternal recognition of the fetal semiallograft and that transforming growth factor-β production may regulate the local maternal immune response and prevent rejection of the fetus. (Am J Obstet Gynecol 1990;163:1430-7.)

Key words: Interleukin-1β, human leukocyte antigen HLA-DRα, transforming growth factor-β, endometrium, placenta

Maternal immunologic recognition of the developing fetal semiallograft is a normal physiologic response during pregnancy and may be important for fetal survival.[1] Several studies have concluded that certain cases of habitual miscarriage are a result of inadequate maternal immune recognition of a fetus whose paternal human leukocyte antigen complement too closely resembles that of the mother.[2,3] Maternal decidua, which is in direct contact with fetal trophoblast, contains a relatively large number of macrophages and lymphocytes.[4] These cell types are capable of complex immunologic interactions, including allograft recognition, which is mediated in part by various cytokines and the major histocompatibility cell surface antigens.[5] Consequently, the regulation of cytokine production and major histocompatibility antigen expression at the maternal-fetal interface may play an important role in maternal immunologic recognition of the fetus and its subsequent survival.

Interleukin-1 (IL-1) is an immunoregulatory protein whose biologic properties include stimulation of T-cell cytokine production, T- and B-cell proliferation, and foreign antigen recognition.[6] There are two forms of IL-1, IL-1α and IL-1β, which have identical biologic activities but are distinctly separate peptides encoded by separate genes. Although the in vivo expression of IL-1 has not been demonstrated for normal endometrium and decidua, it has been reported that term decidua in vitro can produce IL-1α and, to a lesser extent, IL-1β in response to bacterial endotoxin.[7]

HLA-DR is a major histocompatibility type II cell

surface antigen found mainly on activated lymphocytes and cells of monocyte-macrophage lineage. Antigen-presenting cells, many of which are tissue macrophages, couple foreign antigens to HLA-DR and then externalize the immune complex to the cytoplasmic membrane where it is recognized by T and B lymphocytes.[5] The presence of HLA-DR–bearing cells in decidua has been demonstrated by immunohistochemistry.[4] Both HLA-DR and IL-1 expression are important for effective foreign antigen recognition and subsequent lymphocyte activation and proliferation.[5]

Although some degree of maternal immune recognition of the fetus occurs during pregnancy, regulation of the local maternal immune response may be necessary to prevent immune rejection of the fetus. Transforming growth factor-β (TGF-β) is a multifunctional peptide with potent immunosuppresive activities including inhibition of IL-1β–induced lymphocyte proliferation,[8] lymphokine-activated killer cell activity,[9] cytotoxic T-cell activity, natural killer cell activity,[10] and macrophage cytotoxicity.[11] Although both TGF-β[12] and TGF-β[13] messenger ribonucleic acid (mRNA) have been isolated from term placenta, the role of TGF-β in the immunoregulation of the maternal-fetal allograft is largely unexplored.

Because IL-1β, HLA-DR and TGF-β are important immunoregulatory peptides that may play a role in the local maternal immune response to the fetus, this study was designed to characterize the expression of these peptides in tissues found at the maternal-fetal interface during the course of the normal menstrual cycle and during pregnancy.

Material and methods

Tissue samples for this study were obtained from women undergoing elective pregnancy termination by curettage (n = 17), from women with normal cycles undergoing hysterectomy for benign conditions (leiomyomas, nine cases; endometriosis, three, pelvic pain or endometritis, one), and from nonlaboring, uncomplicated repeat term cesarean sections (n = 5). Written consent from the patient and approval by the Institutional Committee on the Right of Human Subjects were obtained before collection of any tissue samples for this study. Placenta and decidualized endometrium from pregnancy terminations were suspended in normal saline solution, washed free of blood, separated under low-power magnification, and frozen in liquid nitrogen within 10 minutes of surgical removal and then stored at −80° C. Endometrium from hysterectomy specimens was scraped from the uterine wall with a scalpel. Within 15 minutes of delivery, term placental membranes and term placental villi dissected free from the decidua basalis were washed in normal saline solution to remove contaminating blood. These tissues were immediately frozen in liquid nitrogen and stored at −80° C. A small portion of the endometrial sample from each hysterectomy specimen was formalin fixed and paraffin embedded; thin sections were stained with hematoxylin and eosin for dating according to the method of Noyes et al.[14] Pregnancy dating was based on a reliable date of the last menstrual period combined with uterine size, ultrasonographic examination, or both of the latter methods.

Northern blot analysis of IL-1β, HLA-DRα, and TGF-β_1. Total ribonucleic acid (RNA) was isolated from the samples by acid guanidinium thiocyanate-phenol-chloroform extraction according to the method of Chomczynski et al.[15] with the following modification. After the final total RNA pellet was dissolved in diethylprocarbonate–treated water, the RNA was further purified by phenol-chloroform extraction followed by chloroform extraction. The RNA was then precipitated with ethanol and pelleted by centrifugation. The final RNA pellet was dissolved in diethylprocarbonate–treated water and the total RNA concentration determined by absorption spectrophotometry at 260 nm.

Total RNA (30 μg) was fractionated by electrophoresis in a denaturing formaldehyde 1% agarose gel in MOPS buffer (0.04 mol/L morpholinopropanesulfonic acid, 10 mmol/L sodium acetate, 1 mmol/L ethylenediaminetetraacetic acid, pH 7.0). The integrity and identical quantity of each RNA sample was ensured by staining the gel with ethidium bromide and visualizing the gel under ultraviolet transillumination. The RNA was transferred to nitrocellulose by capillary diffusion with 20x saline–sodium citrate buffer (SSC) (3 mol/L sodium chloride, 0.3 mol/L sodium citrate, pH 7.0) and then baked at 80° C under vacuum for 2 hours. Prehybridization of the filter was performed with hybridization solution (50% formamide, 0.1% bovine serum albumin, 0.1% Ficoll, 0.1% polyvinylpyrrolidone, 0.1% sodium dodecyl sulfate, 0.1 mol/L sodium phosphate, 100 μg/ml sheared salmon sperm DNA, 0.75 mol/L sodium chloride, 0.75 mmol/L sodium citrate, pH 7.0) for 1 hour at 42° C. The filters were hybridized with 1×10^6 cpm/ml denatured phosphate 32 deoxycytidine triphosphate (^{32}P-dCTP)–labeled IL-1β or HLA-DRα, complementary DNA probes in hybridization solution at 42° C for 16 to 24 hours. Posthybridization washes were performed in 4x SSC, and finally 0.1x SSC (containing 0.02 mol/L sodium phosphate, 0.1% sodium dodecyl sulfate, pH 6.4) for 30 minutes each at 56° C. TGF-β was similarly hybridized and washed except that the hybridization temperature was 56° C and the posthybridization wash temperature was 65° C. The nitrocellulose filters were then exposed to Kodak XAR radiographic film (Eastman Kodak, Rochester, N.Y.) with intensifying screens at −80° C.

A 1.4 kb *Eco*RI cut complementary DNA insert specific for human interleukin-1β (S. Haskill, PhD, De-

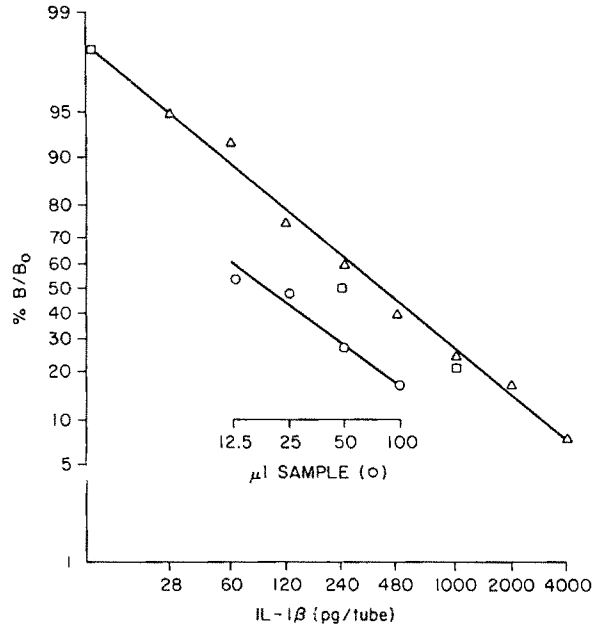

Fig. 1. The logit-log graph of the standard curve for IL-1β (△). To validate the assay, a placental membrane sample was serially diluted (○) in a separate set of experiments and 240 or 1000 pg of standard IL-1β was added to a placental sample (□) and compared with the standard curve.

partment of Obstetrics and Gynecology, University of North Carolina, Chapel Hill), a 3.1 kb *Eco*RI cut genomic clone specific for HLA-DR1 (S. Weissman, MD, Department of Human Genetics, Yale University, New Haven, Conn.) and a 1.05 kb *Eco*RI cut insert specific for human TGF-β_1 (R. Derysnck, PhD, Genentech, Inc., San Francisco) were used as probes in this study. These specific complementary DNA inserts were radiolabeled with ^{32}P-dCTP by random prime oligonucleotide labeling (Pharmacia Oligo Labeling kit, Pharmacia LKB Biotechnologies, Inc., Piscataway, N.J.). The relative expression of IL-1β, HLA-DRα, and TGF-β_1 mRNA was determined by densitometric analysis of the autoradiograms. Statistical analysis was performed with analysis of variance.

IL-1β radioimmunoassay (RIA). To measure IL-1β protein in endometrium, placenta, and placental membranes, 250 mg of tissue was homogenized in 1 ml of phosphate-buffered saline solution pH 7.4 that contained 0.8% 3-[(3-cholamidopropyl)dimethylammonio]1-propanesulfonate, 10 mmol/L phenylmethylsulfonyl fluoride, and 1 mmol/L leupeptin (extract buffer). The samples were centrifuged at 12,000 *g* for 45 minutes at 4° C and the supernatant recovered for IL-1β and total protein determination. Total protein concentration in the supernate was determined in duplicate by means of a standard protein assay (Bio-Rad protein assay, Bio-Rad Laboratories, Richmond, Calif.). IL-1β concentration was determined in the supernate by RIA and expressed as picograms of IL-1β per milligram of total protein. All samples that contained less than the detectable amount of IL-1β in the assay (50 *pg*/100 μl) were assigned the minimal detectable value of 50 *pg*/100 μl sample, and expressed as picograms of IL-1β per milligram of total protein.

The IL-1β RIA used in this study was developed with commercially available reagents. The samples (100 μl) in duplicate and human recombinant IL-1β standards (R and D Systems, Inc., Minneapolis) were incubated with 0.35 μg/ml rabbit antihuman IL-1β IgG (R and D Systems) for 24 hours at 4° C in a total volume of 400 μl of phosphate-buffered saline solution with 0.5% bovine serum albumin, pH 7.4. The samples were then incubated with 100 μl (10,000 cpm, 1000 Ci/mmol) of the iodine 125–labeled human recombinant IL-1β (Amersham Corp., Arlington Heights, Ill.) for an additional 24 hours at 4° C. The samples were then incubated with 100 μl of a 1 : 10 dilution of antirabbit IgG agarose in phosphate-buffered saline solution (Sigma Chemical Company, St. Louis) for 2 hours at room temperature with constant shaking. The bound counts were pelleted by centrifugation with the addition of 1 ml of a 0.125% solution of crystobalite (Manvill Company, Denver) to help maintain pellet integrity. The supernatant was removed and each pellet was counted in a γ-counter. To validate the assay, samples that were either serially diluted or to which known amounts of the IL-1β standard were added were compared with the standard curve to demonstrate appropriate parallelism (Fig. 1). The intraassay coefficient of variability was <10%, and all samples of this study were run in the same assay to eliminate interassay variability. Statistical analysis was performed with analysis of variance.

Characterization of tissue-extractable TGF-β. TGF-β–like bioactivity was extracted from first-trimester gestational endometrium, first-trimester placenta, term placenta, and term placental membranes as previously described.[16] Briefly, 10 gm of tissue was homogenized in concentrated hydrochloric acid/95% ethanol (1 : 50) and then incubated at 4° C for 24 hours. The homogenate was centrifuged and the supernate was then recovered and precipitated overnight at 4° C with the addition of ethanol and ethyl ether. The resulting precipitate was dissolved in 1 mol/L acetic acid and clarified by centrifugation; the supernate was then lyophilized. The lyophilized extract was dissolved in 2 ml of 1 mol/L acetic acid and applied to a 36 × 2.5 cm Bio Gel P-60 column (Bio-Rad Laboratories, Richmond, Calif.) equilibrated in 1 mol/L acetic acid. The column was eluted with a 1 mol/L acetic acid at 12 ml/hour collecting 3 ml fractions. A portion (500 μl) of each

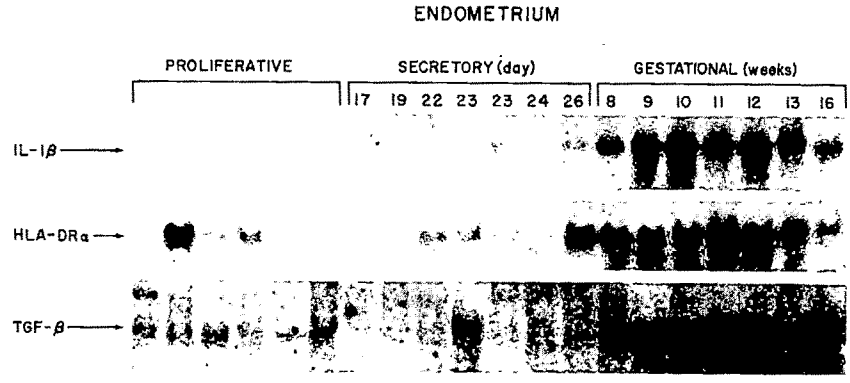

Fig. 2. Northern blot of proliferative, secretory, and decidualized gestational endometrium for IL-1β, HLA-DRα, and TGF-β_1.

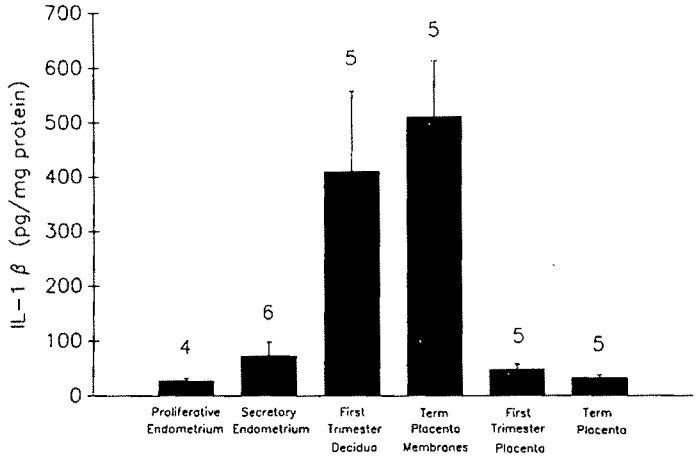

Fig. 3. First-trimester decidua and term placental membranes contain significantly more extractable immunoreactive IL-1β protein ($p < 0.004$) than proliferative endometrium (nondetectable samples, four) and secretory endometrium (nondetectable samples, one), first-trimester placenta (nondetectable samples, five), and term placenta (nondetectable samples, five). *Closed bars* represent the mean levels ± SEM of IL-1β for each group.

column fraction in duplicate was then lyophilized and finally dissolved in 50 μl of 0.01 mol/L hydrochloric acid and used for the TGF-β assay. The tissue extract column fractions were examined for the presence of TGF-β–like bioactivity by the anchorage independent growth assay of normal rat kidney cells (clone 49F).[17] The normal rat kidney cell growth conditions consisted of two layers of media containing agar in 35 × 10 mm culture dishes (Falcon, Becton-Dickinson, Cockeysville, Md.). The bottom layer consisted of 0.6% Bacto-agar (Difco Laboratories, Detroit), 5% fetal calf serum (Gibco, Grand Island, N.Y.), 4 ng/ml epidermal growth factor (Collaborative Research, Inc., Bedford, Mass.), and 50 μg/ml gentamicin sulfate (Sigma) in 1 ml Dulbecco's modification of Eagle medium (Gibco). The top layer was identical to the bottom layer except for a lower Bacto-agar concentration of 0.4% and the addition of 3×10^3 normal rat kidney cells and 50 μl of the fractionated tissue extracts of TGF-β standards (R and D Systems). The plates were then incubated at 37° C in a humidified 95% air/5% carbon dioxide incubator. After 14 days of growth colonies 100 μm or larger were counted and scored. The number of colonies that grew in the fraction sample group were compared with the number of colonies that grew with use of the porcine TGF-β standards and were reported as TGF-β equivalents per fraction.

Results

The IL-1β complementary DNA probe hybridized with a 1.8 kb mRNA species found in decidualized endometrium and term placental membranes. IL-1β mRNA expression was found to be increased twenty-fold ($p < 0.006$) in a decidualized endometrium from

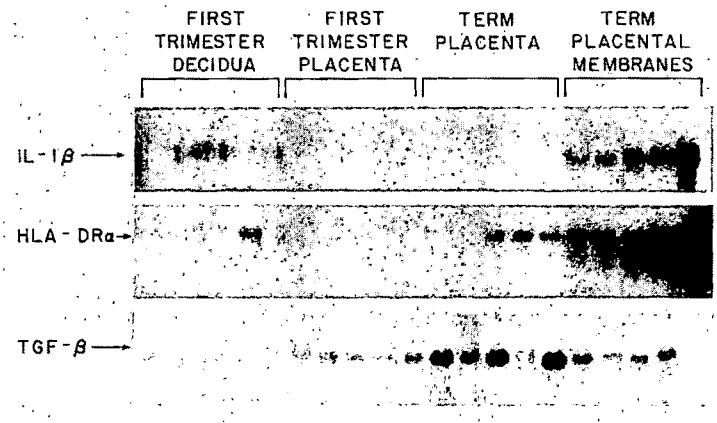

Fig. 4. Northern blot of first-trimester decidua, first-trimester placenta, term placenta, and term placental membranes for IL-1β, HLA-DRα, and TGF-β_1.

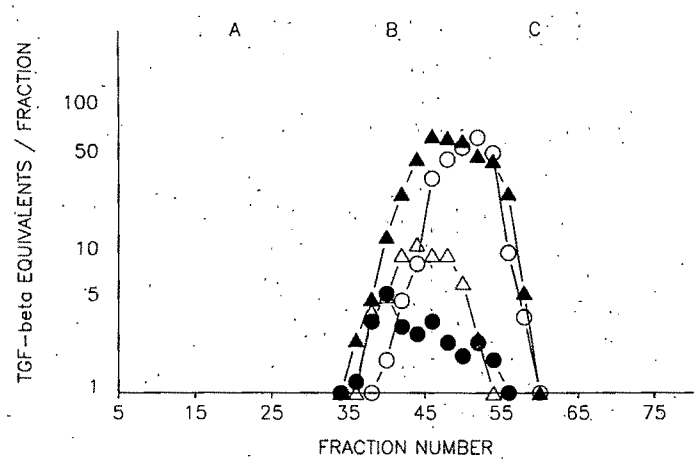

Fig. 5. TGF-β bioactivity found in Bio-gel P-60 column fractions of acid-ethanol extractable protein from decidua (●), first-trimester placenta (△), term placental membranes (○), and term placenta (▲). The column was calibrated with bovine serum albumin (60,000 molecular weight) *(A)*, chymotrypsinogen (27,000 molecular weight) *(B)*, and lysozyme (14,000 molecular weight) *(C)*. One TGF-β equivalent is equal to 1 ng of porcine platelet TGF-β standard.

first-trimester pregnancies when compared with endometrium from the normal menstrual cycle (Fig. 2). Except for a single proliferative endometrial sample that had histologic evidence of endometritis, IL-1β mRNA expression first appeared in secretory endometrium beginning on cycle day 23. All later secretory and gestational decidualized endometrial samples demonstrated IL-1β mRNA expression. Tissue-extractable IL-1β in decidualized gestational endometrium (410 pg/mg total protein) was 7.5-fold ($p < 0.004$) greater than in proliferative endometrium and secretory endometrium (Fig. 3). Term placental membranes, which contain fetal amnion, fetal cytotrophoblast (chorion), and maternal decidualized endometrium, had slightly higher levels of tissue-extractable IL-1β (510 pg/mg total protein) and significantly higher (sevenfold, $p < 0.001$) expression of IL-1β mRNA when compared with first-trimester gestational endometrium (Figs. 3 and 4). Although maternal gestational decidualized endometrium expressed high levels of IL-1β, fetal first-trimester and term placenta expressed little, if any, IL-1β protein or IL-1β mRNA (Figs. 3 and 4).

The HLA-DRα probe hybridized with a 1.6 kb mRNA species found in both maternal and fetal tissues. The relative change in expression of HLA-DRα in endometrium was similar to IL-1β (Fig. 2). HLA-DRα mRNA expression was increased threefold ($p < 0.02$) in gestational endometrium when compared with proliferative and secretory endometrium. However, unlike IL-1β mRNA expression in endometrium, HLA-DRα was also expressed at low levels in most proliferative and secretory endometrial samples. Term placental

membranes expressed slightly higher levels of HLA-DRα mRNA when compared with gestational decidualized endometrium and term placenta, whereas first-trimester placenta had little, if any, HLA-DRα expression (Fig. 4).

Because immune rejection of an allograft is associated with an increase in local tissue expression of both IL-1β and HLA-DR,[18] we looked for the presence of the potent immunosuppressive peptide, TGF-β, in the tissues of the maternal-fetal interface. The TGF-β_1 probe hybridized with a 2.5 kb mRNA species found in both maternal and fetal tissues. TGF-β_1 mRNA expression was increased fivefold ($p < 0.003$) in gestational decidualized endometrium compared with proliferative endometrium and 2.5-fold ($p < 0.002$) compared with secretory endometrium (Fig. 2). Term placental membranes, term placenta, and first-trimester placenta expressed higher levels of TGF-β_1 mRNA when compared with gestational decidualized endometrium (Fig. 3). TGF-β–like bioactivity was detected by normal rat kidney colony formation in soft agar in gestational decidualized endometrium, term placental membranes, and first-trimester and term placenta. Size exclusion chromatography of acid-ethanol extracted proteins resulted in a single broad peak of TGF-β–like bioactivity at approximately 15,000 to 27,000 kd (Fig. 5). Previous studies have shown that under the conditions used TGF-β elutes at a somewhat smaller molecular weight than its true molecular weight of 25,000 kd.[16] Term placenta and term placental membranes had approximately 10 to 20 times more extractable TFG-β bioactivity than did first-trimester decidualized endometrium and term placenta (Fig. 4). Extractable TGF-β bioactivity was not determined in endometrium from the normal menstrual cycle because of the limited amount of tissue available for this study.

Comment

These findings indicate that IL-1β is produced by gestational decidualized endometrium and placental membranes that contain maternal decidua parietalis during the normal course of pregnancy. Both immunoreactive IL-1β and IL-β mRNA levels in endometrium rose significantly during early pregnancy compared with the normal menstrual cycle, suggesting transcriptional regulation of the production if IL-1β in this tissue. Endometrial IL-1β mRNA expression during the normal menstrual cycle first appeared in secretory endometrium beginning on histologic cycle day 23, except for a single proliferative endometrium sample that had evidence of endometritis. Because the process of endometrial decidualization first begins on day 23 of the menstrual cycle,[14] IL-1β may be produced by decidual cells of the endometrial stroma or by the increased numbers of macrophages seen in decidualized endometrium.[4] Unlike maternal decidua, fetal placenta does not produce IL-1β. These findings were unexpected since previous studies have shown that placental tissue explants and isolated cytotrophoblast produce bioactive IL-1 in vitro.[19, 20] It is possible that placenta has the potential to produce IL-1 in vitro given appropriate stimulation, such as adherence to plastic or endotoxin contamination of culture media.[21] Another possibility is that placenta may produce IL-1α and not IL-1β. IL-1α would not be measurable in our IL-1β radioimmunoassay or by our Northern blot analysis. However, IL-1α has the same biologic activities as IL-1β and consequently would be detectable in an IL-1 bioassay. Radioimmunoassay and Northern blot analysis of fresh placenta for IL-1α will be necessary to determine if placenta normally produces this peptide in vivo.

The expression of HLA-DRα, similar to IL-1β, also increased in decidualized endometrium during early pregnancy when compared with endometrium from the menstrual cycle. HLA-DR is composed of an α-subunit and a β-subunit. Because the HLA-DRα subunit has limited polymorphism among most individuals, unlike the highly polymorphic HLA-DRβ subunit, HLA-DRα can be used as a measure of relative HLA-DR expression. These findings are consistent with immunohistochemical localization studies demonstrating an increase in the proportion of HLA-DR–labeled cells in decidua from early pregnancy compared with normal endometrium from the menstrual cycle.[4] It is unclear from this study and previous investigations whether increased HLA-DR expression in decidualized endometrium is a result of increased expression of HLA-DR by resident endometrial cells or is caused by an influx and accumulation of HLA-DR–bearing cells such as macrophages. In addition, there was little, if any, HLA-DR expression in first-trimester placenta, whereas term placenta had marked HLA-DR mRNA expression. Previous immunohistochemical studies would suggest that HLA-DR expression in term placenta is a result of Hofbauer cells of the villous mesenchyme and not the villus trophoblast.[22] Because these cells are separated from maternal decidua by the trophoblast that does not express HLA-DR, allogeneic placental HLA-DR expression probably does not stimulate the local maternal immune response.

Macrophage activation is a predominant feature at sites of immune and inflammatory responses.[5] Macrophages and monocytes express major histocompatibility class II antigens such as HLA-DR, which are important for antigen presentation to T cells. In addition, activated macrophages and monocytes produce a number of cytokines including IL-l, which is an important cofactor in addition to HLA-DR for T-cell activation and recognition of foreign antigens. Antigen-presenting

cells, many of which are tissue macrophages, have been isolated from decidua.[23] The process of endometrial decidualization during early pregnancy is also associated with an increase in the number of macrophages found in this tissue.[4] One possible explanation for our findings is that pregnancy is associated with an influx of activated macrophages into the decidua or that there is an activation of resident decidual macrophages that leads to increased decidual HLA-DR and IL-1β expression.

The beneficial effects that result when the fetal semiallograft provokes an immune reaction by the maternal immune system has been termed "Immunotropism."[24] This theory states that maternal T-cell activation results in the release of various lymphokines that are growth factors for the placenta. Interleukin-3 and granulocyte-macrophage colony-stimulating factor are both secretory products of activated T-cells and stimulate the growth of placental cells in vitro. Because increased decidual IL-1β and HLA-DR expression during pregnancy should lead to local T-cell activation and lymphokine production, our findings are consistent with the immunotropism hypothesis.

Evidence presented in this study that demonstrates TGF-β_1 mRNA and tissue-extractable TGF-β–like bioactivity in decidua, placenta, and placental membranes suggests that this peptide is produced in these tissues. Recent studies have described the potent immunosuppressive properties of TGF-β. The role of TGF-β in regulation of the immune and inflammatory response includes the suppression of lymphokine-activated killer cell activity,[9] inhibition of IL-1–dependent T- and B-cell proliferation,[8] suppression of cytotoxic T-cell activity,[9] and decreased cytotoxicity associated with macrophage activation.[11] On a molar basis, TGF-β is a more potent immunosuppressive agent than cyclosporine.

The beneficial effects of maternal immune recognition without the development of maternal immune rejection of the fetal semiallograft have presented an enigma in the fields of reproduction and transplant immunology. This study has demonstrated that increased IL-1β and HLA-DR expression in maternal endometrium occurs during pregnancy. Although increased IL-1β and HLA-DR expression may be beneficial for T-cell activation and the release of placental immunotrophic growth factors, these are also the initiating events in graft rejection.[18] The production of immunosuppressive peptide TGF-β in the tissues found at the maternal-fetal interface may play a role in the regulation of the maternal immune response and prevent immune rejection of the fetus. The potential role that abnormal production of these immunoregulatory peptides may play in habitual abortion and intrauterine growth retardation is currently being investigated.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Prevalence and determinants of estrogen replacement therapy in elderly women

Jane A. Cauley, DrPH,[a] Steven R. Cummings, MD,[b, c] Dennis M. Black, PhD,[c] Stephen R. Mascioli, MD,[d] and Dana G. Seeley, MS[c]

Pittsburgh, Pennyslvania, San Francisco, California, and Minneapolis, Minnesota

To better understand which women use estrogen replacement therapy, we examined the prevalence and determinants of estrogen replacement therapy in 9704 nonblack women, age ≥65 years, who participated in the multicenter prospective Study of Osteoporotic Fractures. Overall, 13.7% of women reported current use of oral estrogen; 10.9% took estrogen alone and 2.8% took estrogen opposed by progestin. Four percent currently used parenteral estrogen compounds. Current use declined sharply with age from 17% at age 65 to 4% at age ≥85. The primary determinant of estrogen replacement therapy was the type of menopause; the odds of using estrogen replacement therapy in current users compared with never users were approximately five times higher in women with a surgical menopause. Estrogen use was more common among women who had higher levels of education and were less obese. Furthermore, estrogen replacement therapy users were more likely to drink alcohol and to participate in sports and recreation. A diagnosis of osteoporosis was the major determinant of continued estrogen use, but only 24% of women with a diagnosis of osteoporosis used estrogen replacement therapy. We conclude that only a small proportion of elderly women in the United States use estrogen replacement therapy. Selection factors for use of estrogen are evident and may introduce bias in studies of estrogen and disease. In consideration of the distribution of these selection factors, estrogen users will tend to be at lower risk of coronary disease and possibly breast cancer but at greater risk for hip fractures. (Am J Obstet Gynecol 1990;163:1438-44.)

Key words: Estrogen replacement therapy, osteoporosis, coronary disease, breast cancer

Osteoporosis contributes to an estimated 1.5 million fractures per year[1] at an annual cost of at least 7 to 10 billion dollars in the United States.[2] Because the number of individuals 65 years or older will continue to rise, the number of fractures is likely to double by the end of the century.[1] The International Consensus Conference on Osteoporosis[3] concluded that estrogen replacement therapy was the only well-established preventive measure that could reduce the number of osteoporotic fractures.

Coronary heart disease is the leading cause of death in older women and accounts for a large proportion of illness and disability in women 65 years of age and older.[4] Most studies suggest that postmenopausal estrogen use substantially reduces morbidity and mortality from coronary heart disease,[5] although not all studies have observed such benefit.[6]

Because of the potential for prevention of two major causes of morbidity and mortality in elderly women, better understanding of the prevalence of long-term estrogen use in elderly women, as well as the determinants of long-term estrogen use, is essential to assess its public health impact.

Prescriptions for estrogen increased sharply from 1966 to 1975,[7, 8] with the number of dispensed estrogen prescriptions peaking at 28 million per year in 1975, followed by a decline in use until 1981. After the relationship between estrogen replacement therapy and endometrial cancer was reported in 1975,[9] prescriptions for estrogen declined to a low of 14 million in 1980. Since 1981, use of estrogen replacement therapy in the United States has been steadily increasing.[7, 8] Twenty-one million estrogen prescriptions were dispensed in 1986.[8] Most of the previous research on the prevalence of estrogen replacement therapy has examined prevalence rates before 1975,[10-12] and have primarily included women <age 60. Usage rates in elderly women tend to be much lower and to decline with age,[12, 13] but there are few data regarding use of estrogen by older women. The highest rates of use were

observed in upper socioeconomic populations[11, 13] and in whites, compared with both blacks[14] and Mexican-Americans.[15] Geographically, rates tended to be higher in the west than in the east.[8]

Estrogen replacement therapy is not randomly distributed in the population; this could account for some of the observed effects of estrogen replacement therapy on disease outcomes. Estrogen replacement therapy users tended to be less obese,[11, 13] more highly educated,[12] and were more likely to have undergone a surgical menopause.[13] There has been no research on the determinants of estrogen replacement therapy in relationship to potential risk factors for osteoporosis.

In this study, we examined the prevalence and determinants of estrogen replacement therapy in a large cohort of elderly women who participated in the multicenter Study of Osteoporotic Fractures from 1986 to 1988.

Methods

The Study of Osteoporotic Fractures is a prospective multicenter study of risk factors for hip and Colles' fractures in a cohort of 9704 nonblack women aged 65 and older. Subjects were recruited from Oct. 1, 1986, to Oct. 31, 1988, from population-based lists in four areas across the United States: Baltimore, Md., Minneapolis, Minn., Portland, Ore., and the Monongahela Valley near Pittsburgh, Pa. We excluded black women, women with bilateral hip replacement, and those planning to relocate.

Detailed information was collected at baseline on use of estrogen and progestin. "Current" users were women who reported use at the time of the interview. Women were asked to bring all medications to the clinic for verification of use, preparation, and dosage. Information was collected regarding oral and parenteral (skin patches, injections, vaginal creams, suppositories) estrogens and oral progestins. To estimate duration of use, women were asked to check all ages of a chart that listed ages 40 through 100 in which estrogen replacement therapy was used. Duration of use was then calculated by adding the total number of ages that a woman used estrogen replacement therapy.

In addition to estrogen use, the following variables were assessed by questionnaire and interview: medical and reproductive history, personal and family fracture history, alcohol consumption, cigarette smoking, physical activity, demographics, and height and weight at age 25 and at age 50. Women were considered to have had a surgical menopause if they reported a bilateral oophorectomy at the age they stopped menstruating. A positive response to whether a physician had ever told them that they had osteoporosis or brittle bones was interpreted as a previous diagnosis of "osteoporosis." Current body weight was measured on a standard balance beam scale without shoes and heavy outer clothing. Height was measured without shoes with a Harpenden Stadiometer. Waist girth was measured at the midpoint between the bottom of the rib cage and the top of the iliac crest. Hip girth was measured at the widest point—usually at the level of the greater femoral trochanter. Women were considered obese if their body mass index was ≥ 27.3.[16] Women were considered to be upper body obese if their waist to hip ratio was ≥ 0.84.[17]

Statistical analyses were performed using the SAS statistical package.[18] The statistical significance of the univariate association of the dichotomous risk factors to estrogen use was assessed by χ^2 test of the equality of the proportions of women with the risk factor in the three categories of estrogen use.

To adjust for confounding, multivariate logistic analyses were performed. We included as predictor variables selected predictors with a univariate $p < 0.001$, or those that have been shown to have a strong association with estrogen usage in previous research. The same set of predictors was used in four multivariable logistic analyses: current versus never, current versus past for surgical and natural menopause.

Results

A total of 9704 women enrolled in the Study of Osteoporotic Fractures. Characteristics of the participants are described in Table I. The mean age of the subjects was 71.7 years. The majority of the women reported a natural menopause. Information on type of menopause was missing in approximately 5% of the women, and hence, these women are excluded from the multivariate analyses.

Overall, 13.7% of the women reported current use of oral estrogens, and 4% reported current use of parenteral estrogens (Table II). The largest percentage of parenteral users used vaginal estrogen compounds. Of the women currently taking oral preparations (13.7%), 10.9% were taking unopposed estrogen replacement therapy, and 2.8% were treated with combined estrogen-progestin therapy.

The percent of current users of unopposed estrogen therapy varied by type of menopause and by hysterectomy status. Only 9.4% of current users who reported a surgical menopause were taking estrogen replacement therapy opposed by progestins, compared with 25% in women with a natural menopause.

About 4% of women currently using oral estrogen replacement therapy were also using vaginal estrogen. Twenty-seven percent reported past oral use and 12% reported past parenteral use. Current users tended to have initiated oral use at a later age than past users. Current users had taken oral estrogen replacement therapy for an average of 14.8 ± 10.5 years. Current

Duration of use (yr, mean ± SD)		
Current users		6.0 ± 7.2
Past users		2.6 ± 4.8

*Parenteral: Estrogen use by cream, patch, suppository, or injection.

parenteral therapy was started at a later age than oral estrogen therapy.

Use of oral estrogens declined with age (Fig. 1). There was about 40% difference in use among women age 65 to 69 years compared with women age 75 to 79 years. Only 4% of women age 85 and older were currently using oral estrogens. The χ^2 test on the differences in the proportion of current and past users by age was statistically significant, $\chi^2 = 245.6$, $p < 0.0001$.

Current users were more likely to be currently married, to have more years of education, if married, to have a husband with more years of education, to have had a hysterectomy, to have undergone a surgical menopause, to report drinking alcohol, to have ever smoked, to participate in physical activity, to take walks for exercise, and to have ever been pregnant (Table III). Users were less likely to be obese and, more specifically, less likely to be upper body obese. Even at ages 25 and 50 years, current users weighed less than either past users or never users (data not shown).

Although women diagnosed as osteoporotic were more likely to be using estrogen, there was little difference in the proportion of users by whether or not the participant reported any previous fracture after age 50. Users were less likely to report a previous wrist fracture. Women with either a mother or father with a history of fracture after age 50 were more likely to report current or past use of estrogen replacement therapy.

Multiple logistic analyses revealed that the primary determinant of current estrogen replacement therapy use was type of menopause; women with a surgical menopause were more likely to report current estrogen replacement therapy (odds ratio, 4.8; 95% confidence interval, 4.11 to 5.81) compared with never users and were also more likely (odds ratio, 2.30; 95% confidence interval, 1.94 to 2.74) to continue estrogen replacement therapy (current users compared with past users). Because of this strong effect and because of possible bias from selection factors for surgical menopause, we stratified women by type of menopause in subsequent analyses.

In women who had undergone a surgical menopause, current users, compared with never users (Table IV), were younger and were 40% more likely not to be obese, to have greater than a twelfth grade education, and to drink alcohol. In this group, after age, the only significant predictor of continued estrogen replacement therapy (comparing current with past use) was having been diagnosed as osteoporotic.

In women with a natural menopause, a comparison of current with never users with respect to age, education, obesity, and alcohol consumption showed similar results. In addition to these factors, current users were also more likely to have participated in physical activity. However, the strongest determinant of current estrogen replacement therapy in the natural menopause group was having been given a diagnosis of osteoporosis by a physician; current users were 2.8 times as likely to have had a diagnosis of osteoporosis. This diagnosis was also important for determining continued long-term use of estrogen replacement therapy.

Comment

We found that the overall prevalence of estrogen replacement therapy among elderly women is low and decreases with age.

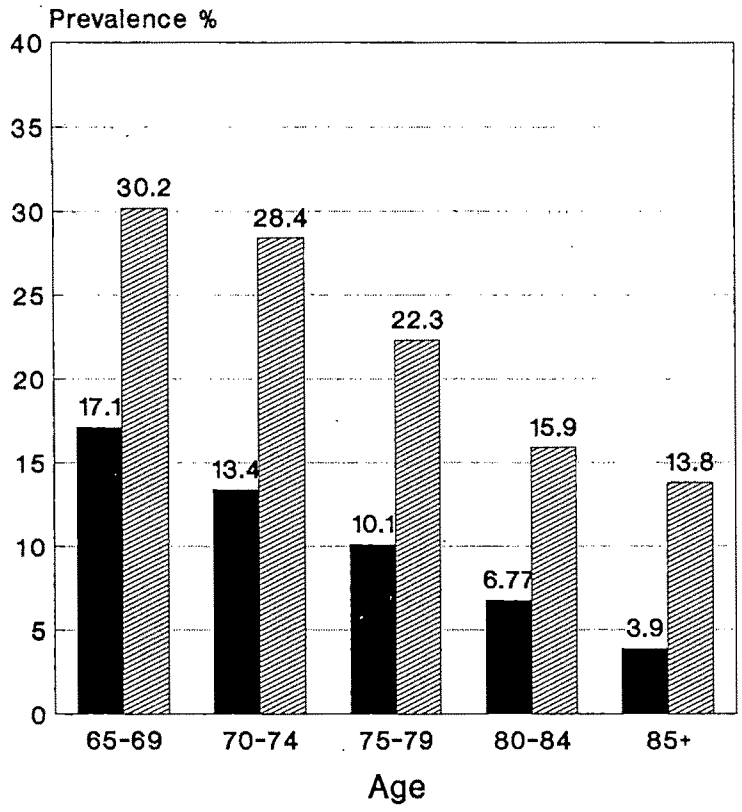

Fig. 1. Prevalence of use of oral estrogen replacement therapy by age, Study of Osteoporotic Fractures (n = 9704). *Solid bars*, Current use; *hatched bars*, Past use.

We recruited subjects from population-based listings in four cities across the United States. However, participants in the Study of Osteoporotic Fractures are not a representative sample of older women; they are volunteers who are likely to be healthier and perhaps more health conscious than those who did not participate. Consequently, our prevalence rates may overestimate rates of use among the general population.

Earlier studies have found determinants of estrogen replacement therapy in younger postmenopausal women. In this study we confirmed that selection factors for estrogen replacement therapy also exist in elderly women. These estrogen replacement therapy characteristics would presumably lower the risk of coronary heart disease, and possibly breast cancer, but increase risk of hip fracture; hence, failure to consider these characteristics leads to bias in studies of the effects of estrogen replacement therapy on coronary heart disease, hip fracture, and breast cancer.

Our results are consistent with previous reports that education level,[14, 15] degree of obesity,[11, 13] alcohol consumption, and surgical menopause[13] are important determinants of estrogen use. Surgical menopause was the strongest predictor of estrogen replacement therapy use in this population of elderly women. We confirmed the results of other studies with regard to no difference in smoking status by estrogen replacement therapy use.[11, 13] Users of estrogen replacement therapy were somewhat more likely to participate in sports and recreation, although this observation was confined to women with natural menopause. This may reflect their higher socioeconomic status and their lower degree of obesity.

Most previous studies on the determinants of estrogen replacement therapy focused primarily on cardiovascular disease risk factors; this study also included possible risk factors for osteoporosis. A diagnosis of osteoporosis by a physician was a significant determinant of current estrogen replacement therapy in women with a natural menopause. Of importance, it was also the strongest determinant of continued long-term estrogen replacement therapy in both the natural and surgical menopause groups; however, the prevalence of estrogen replacement therapy (24%) was low in this potentially high-risk group.

The lack of a relationship between estrogen replacement therapy and previous hip fractures may be related to failure of orthopedists to prescribe estrogen replacement therapy, perhaps because these women are not considered osteoporotic or because many women cannot tolerate or refuse estrogen replacement therapy. Estrogen replacement therapy users were less likely

to report a previous wrist fracture, probably reflecting a protective effect of prior estrogen replacement therapy.

Parental fracture history had a stronger influence on hormone use than personal fracture history. This may be a result of study bias: better educated estrogen users may be more likely to know and report their family history of fracture. It may also relate to the role of women as caregivers since these women may have taken care of elderly parents after fractures and personally experienced the fracture-related decline in functional status or death of a parent.

In an observational population-based study of the effect of estrogen replacement therapy on a disease outcome, the observed low prevalence of estrogen replacement therapy would imply that sample sizes must be large to have adequate statistical power to see a significant effect. Selection factors differ and risk of disease differs in women with a natural versus surgical menopause. Hence, stratification by type of menopause is necessary in evaluating estrogen replacement therapy, and will tend to increase sample size requirements.

Previous research has suggested that some of the protective effects of estrogen replacement therapy on hip fracture and coronary heart disease may be lost within a few years of discontinuing estrogen replacement therapy.[19, 20] For example, Weiss et al.[19] found a significant reduction in risk of hip and wrist fractures in current users only. Discontinuation of estrogen replacement therapy 1 to 2 years before the fracture offered no significant effect. For coronary heart disease,[20] the odds ratio was lower for current users than ever users. Hence, effective prevention of hip fracture and coronary heart disease with estrogen may require

long-term use of estrogen replacement therapy into the seventh, eighth, or even ninth decade of life.

Our data show that few elderly women currently use estrogen replacement therapy. Future research should identify the barriers to long-term use of estrogen replacement therapy. Some possible barriers to estrogen replacement therapy include fear of cancer, unwanted side effects, cost, and polypharmacy (i.e., elderly women may take many other medications for immediate management of medical conditions, and may not want to take one for prophylaxis). It may also reflect physician practices and beliefs. Because of the uncertainty over whether long-term estrogen replacement therapy is associated with breast cancer, physicians may be unwilling to recommend long-term estrogen replacement therapy. If a treatment is known to be effective but is unacceptable to most elderly women, then alternative strategies for prevention must be developed.

Immunocytochemical distribution and localization of 15-hydroxyprostaglandin dehydrogenase in human fetal membranes, decidua, and placenta

Paul Y. C. Cheung. BSc,[a] John C. Walton, MD,[b] Hsin-Hsiung Tai, PhD,[c] Simon C. Riley, PhD,[a] and John R. G. Challis, PhD, DSc[a]

London, Ontario, Canada, and Lexington, Kentucky

Biochemical studies have shown the presence of type I oxidized nicotinamide-adenine dinucleotide–dependent 15-hydroxyprostaglandin dehydrogenase in human fetal membranes, decidua, and placenta. However, the localization of prostaglandin dehydrogenase within these tissues is not known. Because the distribution of prostaglandin dehydrogenase may affect the concentration of prostaglandins that reach the myometrium, we used immunocytochemistry to localize immunoreactive prostaglandin dehydrogenase in fetal membranes and placenta. We also examined whether this distribution changed with labor. Tissues were collected at term elective cesarean section or after term spontaneous labor and delivery, were fixed, embedded, and sectioned at 5 μm. Immunoreactive prostaglandin dehydrogenase was determined with a polyclonal primary antibody to human placental prostaglandin dehydrogenase and visualized with the avidin-biotin procedure. Epithelial and epithelium-derived cells were identified by positive staining with a polyclonal antikeratin primary antibody. Cytokeratin staining was observed in amniotic epithelium, trophoblast layer of chorion, invading trophoblast in decidua, and all subsets of trophoblast in the placenta. Immunoreactive prostaglandin dehydrogenase was localized to the trophoblast layer of chorion, invading trophoblast in decidua, and in syncytiotrophoblast and intermediate trophoblast but not cytotrophoblast in the placenta. In chorion, approximately 50% to 60% of the nonvacuolated trophoblast cells stained positively for prostaglandin dehydrogenase. There was no change in the localization of immunoreactive prostaglandin dehydrogenase in any tissue in association with labor. (AM J OBSTET GYNECOL 1990;163:1445-9.)

Key words: Prostaglandin, metabolism, immunohistochemistry, fetal membranes, placenta

Prostaglandins are strongly implicated in the sequence of events leading to myometrial contractility and parturition at term.[1, 2] In women, amnion and decidua have been identified as major sites of prostaglandin synthesis, whereas the chorion is a major site of prostaglandin metabolism.[3-5] This pattern is reflected in the higher specific activity of the oxidized nicotinamide-adenine dinucleotide–dependent 15-hydroxyprostaglandin dehydrogenase (PGDH) in chorion and placenta compared with the amnion and decidua.[6, 7] This enzyme converts prostaglandins (prostaglandin E_2 and prostaglandin $F_{2\alpha}$) to the 15-keto metabolites, the initial step in inactivating primary prostaglandins. Although previous studies have suggested that small amounts of primary prostaglandins may cross full-thickness membranes without metabolism,[8, 9] the significance of this observation has been questioned because of the high PGDH activity in chorion. However, chorion is a heterogeneous tissue,[10, 11] and it seemed possible that PGDH was not distributed uniformly throughout the tissue. Hence we used immunocytochemistry to determine the distribution and localization of immunoreactive PGDH in the amnion, chorion, decidua, and placenta and determined whether there were changes in the pattern of staining with labor at term.

Material and methods

Collection of tissues. Placentas with membranes and adherent decidua were obtained from uncomplicated pregnancies at either term elective cesarean section before labor ($n = 5$) or at term spontaneous delivery ($n = 5$). Tissues were fixed in either 10% neutral buffered formalin or Bouin's solution for 4 hours, then

washed and stored in 70% ethanol. There was no difference in immunostaining with the different fixatives. The membranes were then rolled and the placenta trimmed before embedding in paraffin wax. The paraffin blocks were then sectioned at 5 μm.

Immunocytochemical analysis. The sections were stained for immunoreactive-PGDH according to the avidin-biotin procedure (Vector ABC; Vector Laboratories, Burlingame, Calif.). Briefly, the sections were deparaffinized with three washes of xylene substitute (BDH Chemicals, Toronto) and rehydrated in serial washes of ethanol, and phosphate-buffered saline solution (0.01/mol/L, pH 7.5). Endogenous peroxidase activity was reduced by the exposure of the sections to 3% hydrogen peroxide in water for 30 minutes. The sections was counterstained with Carrazzi's hematoxylin, which turns the nucleus blue. Nonspecific staining was reduced by incubating the sections in 10% goat serum for 20 minutes. The sections were then incubated overnight with the primary antibody or the appropriate substituted control (see below). The polyclonal primary antibody (1:2000 and 1:3000, Cayman Laboratories, Ann Arbor) was raised in rabbits against purified human placental PGDH. Additional sections were also stained for cytokeratin, which is an epithelial cell marker. The polyclonal primary antibody (antikeratin, wide-spectrum screening; 1:1000, Dako Corp., Santa Barbara) was raised in rabbits against bovine muzzle epidermal keratin. All antibodies were diluted in buffer (1 gm bovine serum albumin, 20 mg sodium azide, 100 ml phosphate-buffered saline solution).

After overnight incubation (18 hours), sections were washed with phosphate-buffered saline solution and incubated in the presence of a biotinylated goat anti-rabbit IgG antibody (1:500) for 1 hour. The sections were then washed, incubated with Vectastain (Vector ABC) for 2 hours and immunoreactive PGDH was visualized by exposure to 3,3′-diaminobenzidine tetrahydrochloride [6 mg dissolved in 4 ml Tris buffer (0.05 mol/L, pH 7.5) with 3 drops of 3% hydrogen peroxide]. The sections were dehydrated and mounted (Permount; Fisher Scientific, Toronto). Sections were examined by means of light microscopy.

It has been suggested previously that the trophoblast layer of chorion at term consists of two subpopulations of trophoblast, vacuolated and nonvacuolated.[10] In chorion, the number of vacuolated and nonvacuolated cells in the trophoblast layer staining positive for immunoreactive PGDH was quantified using the Bioquant System IV (Bioquant; Nashville; field = 0.175 mm^2 at ×250 magnification).[11] Five randomly selected fields were counted in stained sections from each patient and the proportion of stained cells was expressed as a percentage of the total vacuolated and nonvacuolated trophoblasts. Student's *t* test was used to seek significant differences in the number of stained vacuolated and nonvacuolated trophoblast between cesarean section and spontaneous labor tissues.

Controls. Three sets of negative controls were used in this study. Tissue sections were incubated either with antibody dilution buffer in the absence of primary antibody, with nonimmune rabbit serum (1:2000 and 1:3000 dilution), or with primary antibody that had been preabsorbed with purified PGDH[12] overnight. Before use, the preabsorbed antibody was centrifuged at 178,000 *g* for 30 minutes at 4° C, and the supernatant fraction was substituted for the primary antibody in the overnight incubation.

Results

Amnion (Fig. 1, *A* and *C*). In the amnion, positive staining for cytokeratin (data not shown) was found in the epithelial layer but not in the subepithelial layers of tissues obtained from cesarean section or spontaneous labor and delivery. No positive staining for immunoreactive PGDH was observed in the epithelial or subepithelial layers of the amnion in patients undergoing either term elective cesarean section or spontaneous labor and delivery.

Chorion-decidua (Fig. 1, *A* and *C*). Positive staining for cytokeratin (data not shown) was observed only in the trophoblast layer of chorion and in trophoblast cells that had invaded decidua. No staining was found in the reticular or cellular layers of chorion.[13] Positive immunoreactivity for PGDH was observed only in the trophoblast layer of chorion. However, only 50% to 60% of nonvacuolated and <20% of vacuolated trophoblast showed positive immunostaining. There was no significant difference in the percentages of vacuolated and nonvacuolated trophoblast that showed positive immunoreactivity for PGDH between cesarean section and spontaneous labor tissues (Table I). No PGDH immunostaining was found in the reticular or cellular layers or in the degenerative villi of the chorion.

No staining was observed for immunoreactive PGDH in the stromal cells in the decidua. However, trophoblast that had invaded decidua did show positive staining for PGDH. Positive staining for immunoreactive PGDH was eliminated in the negative controls [preabsorption of primary antibody with excess purified antigen (Fig. 1, *B*), antibody dilution buffer without primary antibody, and substitution of primary antibody with nonimmune rabbit serum].

Placenta (Fig. 1, *D*). Positive staining for cytokeratin (data not shown) was found in syncytiotrophoblast, cytotrophoblast, and intermediate trophoblast[14, 15] in both villous and extravillous sites. Intense immunopositive PGDH staining was observed in intermediate tropho-

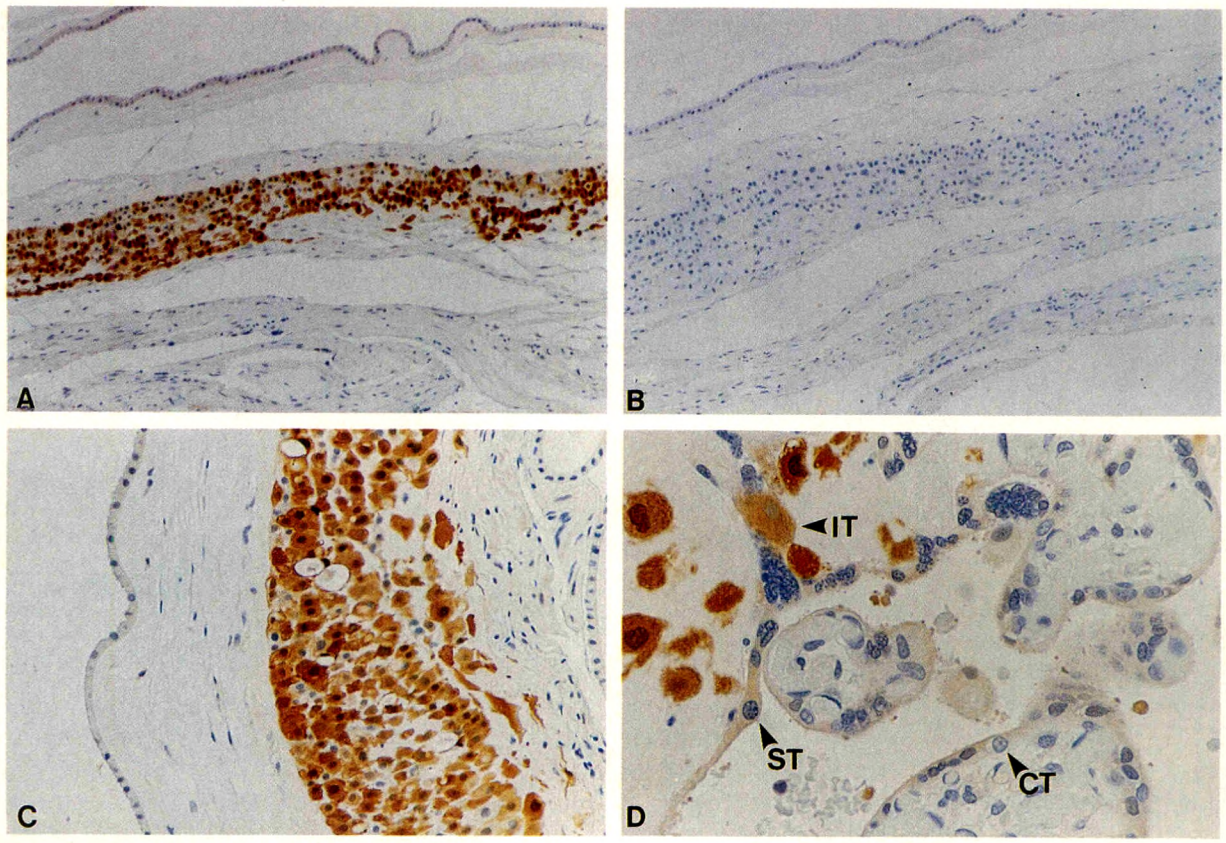

Fig. 1. Staining for PGDH in human fetal membranes, decidua, and placenta. **A,** Full-thickness membranes stained with PGDH primary antibody showed immunoactivity in chorion and invading trophoblast in decidua **(B)** that was abolished by preabsorbing the primary antibody with purified PGDH. **C,** Higher-power section through membranes shows vacuolated and nonvacuolated trophoblast staining. **D,** Section through placenta shows positive immunostaining in intermediate trophoblast *(IT)*, syncytiotrophoblast *(ST)*, and lack of staining in cytotrophoblast *(CT)*. (Original magnifications: **A** and **B,** ×67; **C,** ×133; **D,** ×267.)

blast cells in villous and extravillous sites. Weak positive staining was found in syncytiotrophoblast. Positive immunostaining was abolished in all negative controls. We did not observe PGDH immunostaining in the cytotrophoblast, villous core tissue, or fetal endothelial tissue. Similar patterns of PGDH staining were observed in placentas obtained at both cesarean section and spontaneous labor and delivery.

Comment

This study reports, for the first time, localization of immunoreactive PGDH in the fetal membranes, decidua, and placenta. In the membranes PGDH was present in the trophoblast layer of chorion, in approximately 55% of the nonvacuolated cells, but was absent from amnion and decidual stromal cells. In the placenta PGDH was localized to intermediate trophoblast, weakly to syncytiotrophoblast, but was absent from cytotrophoblast.

Table I. The percentage of vacuolated and nonvacuolated trophoblast cells showing positive immunoactivity for PGDH in the trophoblast layer of the chorion laeve*

Cell type	*Percentage*	
	Spontaneous labor plus delivery (n = 5)	*Cesarean section (n = 5)*
Vacuolated trophoblast	10.0 ± 2.0	15.0 ± 7.0
Nonvacuolated trophoblast	55.0 ± 4.0	53.0 ± 4.0
Total vacuolated trophoblast cells in trophoblast layer	26.0 ± 6.0	10.0 ± 4.0
Total nonvacuolated trophoblast cells in trophoblast layer	74.0 ± 6.0	90.0 ± 4.0

*The percentage of vacuolated and nonvacuolated trophoblast cells occupying the trophoblast layer is also shown (mean ± SEM).

We used cytokeratin staining to identify epithelial and epithelial-derived cells, including trophoblast.[16] Colocalization of PGDH and cytokeratin was not attempted in this study; therefore we cannot state definitively whether all invading trophoblast in the decidua or intermediate trophoblast in the placenta[14, 15] stained for PGDH. However, the cells staining immunopositive for PGDH in these locations had morphologic characteristics of intermediate trophoblast. Intermediate trophoblast also stain positively for human placental lactogen and pregnancy-specific β_1-glycoprotein, but not for human chorionic gonadotropin, thereby distinguishing them from cytotrophoblast and syncytiotrophoblast.[14] We believe that the PGDH staining observed in this study is specific because it was absent after preabsorbing the primary PGDH antibody with a purified PGDH preparation, and no positive staining was found if the primary antibody was omitted, or replaced with nonimmune rabbit serum.

The distribution of PGDH immunostaining is generally consistent with the biochemical distribution of PGDH activity in the fetal membranes.[4] The enzyme is absent from amnion, predominant in chorion, and present at low activities in decidua.[4, 17] The finding that trophoblast invading into decidua stained for PGDH raises the possibility that these cells are responsible for the PGDH activity found in dispersed cell preparations of decidua that were prepared by scraping it from the chorion. Clearly, separation of chorion and decidua cannot be accomplished without contamination by this simple mechanical procedure, and reports of decidual PGDH activity[17] must be regarded with some suspicion.

Our results suggest that the high PGDH activity present in the placenta[6, 7, 18] may be localized to intermediate trophoblast cells, and to syncytiotrophoblast, but not to cytotrophoblast or villous stromal tissue. It has been suggested that human placental PGDH is partially dependent on fetal genotype[19] and may be inhibited by progesterone,[20] as in the fetal lung,[21] or by estrogen.[20] An endogenous inhibitor of placental PGDH has also been reported,[22] but there is lack of change in PGDH activity with labor,[23, 24] which suggests that it is not a major regulatory factor contributing to the levels of bioactive primary prostaglandins. We did not observe differences in the localization of immunoactive PGDH in placenta or membranes with labor. Thus our results would be consistent with the view that changes in PGDH distribution or activity are unlikely to contribute to the increase in prostaglandin concentration at parturition. Prostaglandin H_2 synthase has also been localized primarily to syncytiotrophoblast and intermediate trophoblast, and similarly, its distribution did not change with labor.[25] However, placental PGDH could influence the amount of primary prostaglandins produced within the placenta that reaches the underlying decidua, myometrium, or both.

In late human pregnancy, amnion is a major site of prostaglandin E_2 production.[1-5] It has been suggested that primary prostaglandins may cross the fetal membranes from amnion to decidua or myometrium for subsequent biologic effects.[8, 9] Because of the high metabolic activity in chorion it has been suggested and subsequently shown[9] that this transfer likely takes place via the intercellular spaces. However, this study shows that PGDH is distributed heterogeneously in chorion. Thus we suggest that the chorion may not present the uniform metabolic barrier to prostaglandin transfer that previously had been assumed.

The effect of physical activity during pregnancy on preterm delivery and birth weight

Mark A. Klebanoff, MD, MPH,[a] Patricia H. Shiono, PhD,[b] and J. Christopher Carey, MD,[c]

Bethesda, Maryland, Los Altos, California, and Oklahoma City, Oklahoma

The relationship between physical activity during pregnancy, preterm birth, and gestational age–adjusted birth weight was investigated prospectively in a cohort of 7101 women. This study is one of few to evaluate both employment- and non-employment-related physical activity. Prolonged periods of standing were associated with a modestly increased risk of preterm delivery (adjusted odds ratio for ≥8 hours/day of standing = 1.31). Heavy work or exercise was not associated with preterm delivery (adjusted odds ratio for ≥4 hours per day of heavy work = 1.04). The proportion of infants born preterm did not differ among women working in predominantly standing, active, and sedentary occupations. Physical activity was not associated with gestational age-adjusted birth weight after controlling for confounding variables. These data suggest that unmeasured socioeconomic differences among women reporting different levels of activity may account for previously described associations between physical activity and pregnancy outcome. Most pregnant women who report increased levels of physical activity are not at increased risk of preterm delivery or reduced intrauterine growth. However, these data do not address the role of activity restriction in the management of selected women at high risk for adverse pregnancy outcome. (Am J Obstet Gynecol 1990;163:1450-6.)

Key words: Infant, low birth weight; labor, premature; women, working; work

The effect of physical activity during pregnancy on preterm delivery and fetal growth has been controversial. Mamelle et al.[1] stated that as the number of fatigue factors among women employed during pregnancy increased from 0 to 5, the rate of premature birth increased from 2.3% to 11.1%. Among hospital workers, work-related factors (long periods of standing, carrying heavy loads, and performing heavy cleaning tasks) were observed to be associated with preterm delivery.[2] Compared with women whose occupations entailed varied amounts of physical activity, women employed in occupations requiring long periods of standing were found to be 2.7 times as likely to be delivered before term, and women employed in sedentary occupations were 1.4 times as likely to be delivered preterm.[3] In contrast, other studies have found the usual range of physical activities performed by pregnant women to be unassociated with gestational age–adjusted birth weight,[4] mean gestational length,[4] or preterm delivery.[5] However, only two studies considered non-employment-related physical activity.[4, 5] This study determines the relationship between physical activity and pregnancy outcome in a prospective cohort of women.

Material and methods

The Vaginal Infections and Prematurity (VIP) study is a prospective study, sponsored by the National Institute of Child Health and Human Development and the National Institute of Allergy and Infectious Diseases, to determine the association between genital tract carriage of various microorganisms and preterm birth. The population consisted of women who received prenatal care at one of five clinical centers (Columbia University, New York; University of Washington, Seattle; University of Oklahoma, Oklahoma City; University of Texas, San Antonio; Louisiana State University, New Orleans) from 1984 to 1987.

Women who were at least 16 years old and did not have one of the exclusion criteria (diabetes requiring insulin, hypertension or heart disease requiring medication, chronic renal disease, multiple pregnancy, Rh sensitization, current use of corticosteroids, history of

cervical incompetence or cerclage, receipt of antibiotics within the 2 weeks preceding interview, previous treatment with tocolytic agents between the beginning of the pregnancy and the date of interview, and intent to deliver at a non–study hospital) were interviewed at 23 to 26 completed weeks' gestation about a variety of risk factors for adverse pregnancy outcome. The interview included the question "In a typical day during the first 5 months of pregnancy, about how many hours did you spend doing the following?" Activities included "standing for long periods of time, heavy work/exercise" (sufficient to cause sweating), and "light work/exercise." These activities were asked with reference to the entire day, as opposed to on the job only. For these analyses, times were classified a priori as 0, 1 to 3, 4 to 7, and ≥8 hours per day. Few women reported engaging in heavy work for ≥8 hours per day; therefore the two highest categories were combined for heavy work.

Gestational age at screening for study eligibility (23 to 26 weeks) was determined according to the attending obstetrician's best estimate. This estimate was based on the last menstrual period, supplemented by other clinical evidence including ultrasonograms, uterine measurements, and detection of fetal heart tones. Gestation at delivery (in completed weeks) was calculated from this initial estimate and the elapsed time from screening to delivery.

The associations between risk factors for adverse outcome and activity level were evaluated by χ^2 analysis. The relative risk of preterm delivery by level of activity was approximated by odds ratios[6]; 95% confidence intervals was calculated with Woolf's method.[7] The odds ratios for preterm delivery were adjusted for the confounding variables listed in Table I by means of multiple logistic regression.[6] Because many hours of one type of activity might exert their effect by precluding the possibility of another activity, the final regression model contained terms for all types of work; results from this model were nearly identical to those obtained from three separate models, each limited to one type of activity.

The association between preterm birth and occupational characteristics was investigated to replicate the analysis of Teitelman et al.[3] Each woman's current occupation was classified according to the United States Census Bureau 1980 codes.[8] Only women whose job titles were identical to those used previously[3] were included. The risk of preterm birth was compared among women whose jobs were considered predominantly standing, active, or sedentary by this classification.

Finally, we studied the effect of reported physical activity on fetal growth. Mean gestational age–adjusted birth weight was calculated by means of a two-way analysis of variance for each level of reported physical activity. These mean birth weights were further adjusted for confounding factors using analysis of covariance.

Results

From Nov. 1, 1984, to June 30, 1987, 8287 women were enrolled in the VIP study; data on the duration of pregnancy were available for 7578 women. Missing data were caused by loss of the woman to follow-up between study entry and delivery. Extensive efforts were made to locate study women and obtain at least the date of delivery and birth weight and sex of the infant. These efforts, which were unsuccessful for 709 women, included attempted contact at the last known address, querying other hospitals in the region, and in many cases attempting to locate the birth certificate at the county health department. Early in the study, the questions regarding physical activity were revised; the original questions were not comparable with the revised ones, and women whose data were contained on these early forms were deleted (n = 256). Women whose ethnicity was other than white, black, or Hispanic were excluded (n = 207), as were women with no data on amount of physical activity (14 for standing, 14 for light work, 15 for heavy work). The final population comprised 7101 women for the study of standing and light work, and 7100 for heavy work. The characteristics of the study population are presented in Table I.

Women who reported long hours of heavy work had demographic profiles similar to those who reported long hours of standing.* Prolonged heavy work and standing were both more common among women at the San Antonio center, among Hispanic women, and among parous women. Women with increasing education, women under 20 years of age, women who were never married, and women who currently smoked were more likely to report no heavy work or prolonged standing. Longer hours of heavy work and standing were most prevalent among women who might be called the "working poor": currently employed, total household incomes of $10,000 to 14,999 per year, currently married or married at some time in the past, and self-payment for medical care.

Women who spent more time doing light work differed in these characteristics from women doing heavy work and standing. Increasing time spent doing light work was most prevalent among women in New York City and Seattle, white women, women aged 25 to 29 years, currently married women, and parous women. Longer hours of light work were more prevalent among women of higher socioeconomic status than were longer hours of heavy work and standing. Higher socioeconomic status was reflected in household incomes of ≥$20,000, currently working, more than 12 years of education, and having private medical insurance.

The relationships among preterm birth and hours spent in standing, heavy work/exercise, and light work/exercise were generally modest (Table II). In the unadjusted analysis women who spent more time standing had a modestly increased risk of preterm birth. Women who spent ≥8 hours/day standing were approximately 28% more likely to give birth before 37 completed weeks' gestation than women who reported no standing. Women who performed ≥4 hours/day of heavy work were 20% more likely to be delivered preterm than women who did no heavy work. Women who engaged in light work were less likely to be delivered before term. To determine whether local differences in physical activity accounted for the results, the associations between reported activity and preterm delivery were evaluated separately for each center. In no center were the results substantially different* from those in Table II.

The adjusted relationships between various risk factors and preterm delivery are presented in Table III. Preterm delivery was significantly more common among black women (odds ratio compared with white women = 1.28; 95% confidence interval = 1.01 to 1.63), women who smoked at the time of interview (odds ratio compared with nonsmokers = 1.47; 1.23 to 1.75), and women in Texas (odds ratio compared with Columbia = 1.51; 1.11 to 2.05). The relationship between household income and preterm delivery was complex; preterm delivery decreased with increasing income up to $15,000 to 19,999 per year (odds ratio compared with <$5000 = 0.36), then rose again to reach values similar to those for women in the lowest category (odds ratio for ≥$30,000 = 0.90). The other factors in Table III were not significantly associated with preterm birth.

Long hours of standing remained significantly associated with preterm birth, although the effect was modest (adjusted odds ratio = 1.31; 1.01 to 1.71). The trend for increasing preterm birth with increasing time standing was of borderline statistical significance. Heavy work was not associated with preterm birth. However, increasing time spent doing light work or exercise retained its significant negative association with preterm birth.

Among the VIP study population, 1778 women (25% of the total) were working at 23 to 26 weeks' gestation; 1252 (70%) were employed in jobs with titles that were

ferent from any of the others; adjustment for the factors in Table III had little effect on these results.

To determine the degree to which active, standing, and sedentary jobs were associated with reported activity, the mean hours of standing, light work, and heavy work were compared for women employed in the three types of jobs. Women employed in active, standing, and sedentary jobs reported 4.5, 5.6, and 1.7 hours of prolonged standing ($p < 0.0001$ by analysis of variance); 1.1, 0.7, and 0.3 hours of heavy work ($p < 0.0001$); and 6.1, 5.2, and 5.7 hours of light work ($p = 0.0002$). These data indicate that although the job classifications are somewhat associated with reported activity, the associations are not strong, possibly because they fail to consider nonoccupational physical activity.

To investigate the possibility that errors in calculation of gestational age contributed to the inability to find a strong association of preterm birth and level of strenuous activity, the relationship between activity and low birth weight (<2500 gm) was investigated. The percentage of infants with low birth weights among women reporting 0, 1 to 3, 4 to 7, and ≥8 hours of standing were 7.3%, 7.5%, 7.8%, and 7.6%, respectively. The corresponding figures for light work were 12.4%, 7.3%, 7.8%, and 6.8%. Among women reporting 0, 1 to 3, or ≥4 hours per day of heavy work, the low birth weight percentages were 7.5%, 7.5%, and 7.3%, respectively.

Activity might have a greater effect on fetal growth than on length of pregnancy. To investigate this possibility, we calculated the mean gestational age–adjusted birth weight for infants of women in each activity group. Mean gestational age–adjusted birth weight did not vary significantly with reported hours of standing or heavy work (p values for trend 0.48 and 0.22, respectively). Increasing time spent doing light work was associated with increased gestational age–adjusted birth weight in the unadjusted analysis, increasing from 3181 gm for women reporting 0 hours of light work to 3300 gm for women reporting ≥8 hours of light work (p for trend = 0.048). After adjustment for the factors listed in Table I, standing, heavy work, and light work were not associated with gestational age–adjusted birth weight (Table IV).

Comment

This study found that women who reported long hours of standing had a slightly increased risk of preterm delivery. Heavy work was not associated with an increased risk of preterm delivery, and light work demonstrated a negative association with preterm delivery. These findings are in general agreement with those of Berkowitz,[9] who noted that an absence of leisure time physical activity was a risk factor for preterm birth, and who did not find a wide variety of measures of physical activity to be associated with preterm birth.[5] Occupational activity was not related to mean birth weight or gestational age in other studies.[10]

These results disagree with those of previous studies[1-3] that found occupational factors, including prolonged standing, to be strongly associated with preterm birth. Both our study and that of Teitelman et al.[3] were prospective; activity data were collected before delivery. The other reports were based on retrospectively ascertained data.[1, 2] Our study differs from the former studies[1-3] in one important respect: data on activity were not limited to occupational factors, but included all physical activity. However, when only occupational factors were considered, no difference in preterm delivery was found among women employed in standing, active, and sedentary jobs. We obtained occupational data at the end of the second trimester, when physical activity would be expected to exert its greatest effect; Teitelman

et al.[3] obtained most occupational data during the first trimester. Differential rates of quitting work as pregnancy progressed were less likely to be of concern in our study.

There is no obvious reason to explain why we were unable to replicate the results of Teitelman et al.[3] and Mamelle et al.[1]; a possible explanation may be the socioeconomic difference between the study populations. The New Haven and French populations comprised a broad cross-section of women with widely varying occupations. In those settings, reported occupational physical activity may have been a surrogate for the more difficult to measure social class. Our predominantly clinic-based population demonstrated relatively little socioeconomic variability; 68% of women whose household income was known earned <$10,000 per year and only 17% had private health insurance. This relative socioeconomic homogeneity may account for the minimal effect of physical activity, both occupational and total, on preterm birth. Alternatively, the generally high-risk nature of the VIP population, with a preterm delivery rate of approximately 10%, may have obscured a subtle effect of physical activity on preterm birth.

It could be argued that women employed in jobs that required prolonged standing were more likely to quit work as pregnancy advanced, thereby reducing their risk of adverse outcome. The VIP protocol called for random samples of women with uncomplicated pregnancies to undergo an abbreviated reinterview at 31 to 33 and 34 to 36 weeks. Of the 1252 women employed in classifiable occupations[3] at 23 to 26 weeks, 156 were reinterviewed. Sixty-seven percent of women with jobs requiring prolonged standing were still working, compared with 55% of those with active and 78% of those with sedentary jobs. Therefore the absence of an increased risk of preterm delivery among women with jobs that require prolonged standing is not a result of their likelihood to quit work earlier in pregnancy than women with other jobs.

Reported physical activity was not associated with gestational age–adjusted birth weight. This is in agreement with Rabkin et al.,[4] who collected extensive prospective data on total physical activity at 17, 28, and 36 weeks' gestation. They found no associations between activity at either paid work or house work at any of the three time points and birth-weight-for-gestational age. Our results are also similar to those of Zuckerman et al.,[10] who found no difference in mean birth weight among women employed in standing occupations, other occupations, and unemployed women.

In summary, we studied the effect of physical activity on the subsequent development of preterm birth and on gestational age–adjusted birth weight. Women engaged in prolonged periods of standing were at slightly increased risk of preterm delivery; heavy work or exercise was not associated with preterm delivery. Women who engaged in light work or exercise during the first 5 months of pregnancy were at reduced risk of preterm delivery. The percentage of infants born before term did not differ among women engaged in predominantly standing, active, and sedentary occupations. Gestational age–adjusted birth weight was not associated with reported hours of standing, heavy work, or light work. These results cast doubt on the association between physical activity of the type usually practiced by pregnant women and either duration of pregnancy or gestational age–adjusted birth weight, and raise the possibility that unmeasured socioeconomic differences between women reporting different levels of activity may account for previous positive findings on this subject.

Although little risk was observed for physical activity and preterm birth, there may be a place for activity restriction among women who experience pregnancy complications. However, activity restriction may have unanticipated adverse consequences. Employed women may face a dilemma: they may be forced to work to retain pay and medical benefits, thereby risking the pregnancy, or they may quit working and lose pay, benefits, and perhaps the job. Women with other children or household responsibilities may be unable to restrict their activity despite the possible threat to their pregnancy. Unfortunately, these issues are not easily resolved.

The VIP study group consists of the following:

Prenatal diagnosis of laryngeal atresia

William J. Watson, MD, John M. Thorp, Jr., MD, Richard C. Miller, MD, Nancy C. Chescheir, MD, Vern L. Katz, MD, and John W. Seeds, MD

Chapel Hill, North Carolina

In a patient in whom preeclampsia developed at 23 weeks' gestation, ultrasonographic examination of the fetus showed enlarged edematous lungs, a compressed fetal heart, severe ascites, fetal hydrops, and placental edema. Autopsy of the hydropic stillborn infant showed laryngeal atresia. The ultrasonographic appearance of this rare malformation is presented. (Am J Obstet Gynecol 1990;163:1456-7.)

Key words: Laryngeal atresia, prenatal diagnosis, hydrops fetalis

Laryngeal atresia is a rare congenital malformation that is incompatible with life. Antenatal diagnosis of this malformation is possible because of the secondary structural changes in the fetus that result from this condition. This report details the ultrasonographic findings and prenatal course of a patient whose fetus had laryngeal atresia.

Case report

A 34-year-old woman, gravida 3, para 1-0-1-1, was first seen for prenatal care at 7 weeks' gestation. At 15 weeks' gestation an ultrasonographic examination showed normal fetal anatomy and the patient chose to have an amniocentesis because of increased maternal age. Amniotic fluid α-fetoprotein was 0.8 multiples of the median, and the karyotype was 46,XX. At 23 weeks' gestation, the patient's blood pressure was 146/90 mm Hg and she had gained 8 pounds in 1 week. Repeat ultrasonographic examination showed a hydropic fetus with massively enlarged lungs, a compressed heart that appeared structurally normal (Fig. 1), severe ascites, and scalp edema. The placenta was thick and echogenic, and the amniotic fluid volume was decreased. Significant laboratory values included a uric acid level of 7.1 gm/dl and aspartate aminotransferase of 32 U/L (normal, 9 to 26 U/L). There was no proteinuria. Laboratory evaluation for hydrops included a negative antibody screen, and negative toxoplasmosis, rubella, cytomegalovirus, herpes simplex, and parvovirus titers.

A diagnosis of preeclampsia was made and induction of labor was accomplished for maternal indications with prostaglandin E_2 suppositories. A severely hydropic stillborn 1650 gm female fetus was delivered. At autopsy, laryngeal atresia was found. The fetal lung was hyperplastic and weighed 70 gm (normal, 15 gm). There was massive ascites, with 1000 ml of peritoneal fluid. Duodenal atresia was also noted. The placenta weighed 560 gm and showed hydropic change.

Fig. 1. Fetal chest at level of four-chamber view. Massive enlargement of fetal lung is seen, causing compression of heart.

Comment

The most striking ultrasonographic finding in this fetus at 23 weeks' gestation was the enlarged echogenic fetal lung (Fig. 1). The hyperplastic lung results from fetal lung secretions that accumulate in the tracheobronchial tree. It has been hypothesized that excessive retention of liquid in the lung, as is seen with laryngeal atresia, promotes lung growth.[1] The fetal lung compression on the heart, great vessels, and thoracic duct may have caused the fetal hydrops.

We were able to find one previous report of the ultrasonographic appearance of laryngeal edema—in the Japanese literature.[2] This patient had a normal ultrasonographic examination at 18 weeks, but at 22 weeks' gestation ascites and enlarged echogenic lung were found. She eventually was delivered of a 2578 gm infant who died shortly after birth after failed attempts at intubation.

Factors that influence amniotic fluid volume in this condition may include the presence of other associated anomalies and the degree of esophageal and stomach compression from ascitic fluid.

Included in the differential diagnosis of a fetus with enlarged echogenic lungs is type III congenital cystic adenomatoid malformation of the lung, which may also be associated with fetal hydrops. However, this lesion is usually unilateral.

Direct visualization of the fetal larynx with ultrasonography to diagnose atresia is probably not possible at present, but the secondary structural changes in the fetal chest that result from this rare lesion are distinctive and may make antenatal diagnosis of this malformation possible. Ultrasonographic recognition of these characteristic changes may not be possible until after the middle of the second trimester because ultrasonography earlier in pregnancy showed normal fetal anatomy.

Correlations between antepartum maternal metabolism and newborn behavior

Thomas Rizzo, PhD,[c, d] Norbert Freinkel, MD,[a, b, d, †] Boyd E. Metzger, MD,[a, d] Roger Hatcher, PhD,[c, d] William J. Burns, PhD,[c, d] and Peter Barglow, MD[c, d]

Chicago, Illinois

We suggested that antepartum maternal metabolism may affect later cognitive and behavioral function of progeny by impacting on developing brain cells in utero. This study reports on the observed relationships between serial characterizations of maternal fuels during pregnancy and Brazelton neonatal behavioral assessment scale ratings of offspring from 73 well-controlled pregestational diabetic patients, 112 gestational diabetic patients, and 24 nondiabetic patients. After controlling for the effects of premature birth on the Brazelton neonatal behavioral assessment scale, significant correlations were found between second- and third-trimester glycemic regulation (hemoglobin A_{1c} and fasting plasma glucose levels) and three of four newborn behavioral dimensions of the Brazelton neonatal behavioral assessment scale. In each case, as maternal glucose increased, the newborns' Brazelton neonatal behavioral assessment scale responses were poor. Results were not substantially different when gestational and pregestational diabetic patients were analyzed separately, nor can they be attributed to various perinatal events (neonatal asphyxia, hypoglycemia) or differences in socioeconomic status or ethnicity. The presence of fuel-related neurobehavioral deficits in neonates of diabetic mothers suggests that such infants start their interactions with care givers from a modified base. (Am J Obstet Gynecol 1990;163:1458-64.)

Key words: Behavioral teratogenesis, fuel-mediated teratogenesis, offspring of diabetic mothers, newborn behavior

Most maternal fuels gain access to the developing fetus in a concentration-dependent fashion throughout pregnancy.[1] As a consequence, fuel metabolism in the mother may determine the quantitative and qualitative characteristics of the nutrient mixture in which the fetus develops in utero.[1, 2] This tissue culture aspect of pregnancy prompted the suggestion that maternal fuel economy may influence long-range characteristics of the progeny by modifying the phenotypic gene expression of poorly replicating or terminally differentiated cells during embryogenesis or fetal development.[3, 4] Freinkel[3, 4] designated the developmental possibilities as "fuel-mediated teratogenesis" and hypothesized that the long-range manifestations would depend on the cells in the fetus undergoing differentiation, proliferation, or functional maturation at the time of the disturbance in maternal fuels.

We initiated a program at Northwestern University Medical School in 1977 to test for fuel-mediated teratogenesis on a prospective basis. Diabetes was chosen as the operational paradigm because maternal fuels undergo the greatest perturbation in this condition. Thus all women with pregnancies complicated by diabetes mellitus who were seen at Prentice Women's Hospital and Maternity Center of Northwestern Memorial Hospital between September 1977 and February 1983, and a smaller number of pregnant women with documented normal carbohydrate metabolism, were given the opportunity to participate in this prospective study. They were enrolled in the Northwestern University Diabetes in Pregnancy Center, and serial estimates of circulating maternal fuels were obtained throughout the antepartum management as a data base against which the project detailed examinations of the offspring at birth and during infancy and childhood.

All gravid women with diabetes were given diabetes care consistent with the prevailing state of the art including multiple insulin injections each day. Thus severe metabolic abnormalities were not encountered in any participant during the 1977 to 1983 period of enrollment, and a perinatal mortality rate of 1.9% was achieved even in the patients with insulin-dependent diabetes mellitus. Nevertheless, we have been able to show some distinct correlations between antepartum fuel metabolism and a number of subsequent charac-

teristics of the offspring[5] thereby attesting to the exquisite sensitivity of fuel-mediated teratogenesis.

This manuscript summarizes the relationship between maternal fasting plasma glucose, hemoglobin A_{1C} (HbA_{1C}), and β-hydroxybutyrate during the second and third trimesters of pregnancy and neonate performance on the Brazelton neonatal behavioral assessment scale.[6] Portions of this manuscript were reported previously in abstract form.[7]

Material and methods

Subjects. Subjects were 209 pregnant women and their singleton neonates. Seventy-three gravid women had known diabetes that antedated the pregnancy, that is, pregestational diabetes mellitus, 112 gravid women had "glucose intolerance with onset or first recognition during pregnancy"[8] that is, gestational diabetes mellitus, and 24 gravid women had normal gestational carbohydrate metabolism (nondiabetic patients) as documented by oral glucose tolerance according to the criteria of O'Sullivan and Mahan.[9] We excluded all women who required medication on a chronic basis for the treatment of medical or psychiatric problems or who were seriously noncompliant (i.e., repeatedly failed to complete scheduled tests, keep clinic appointments, or maintain written records of home monitoring for urinary glucose, acetone, or capillary blood sugar levels as this became available). All participants gave informed written consent, and detailed demographic and socioeconomic data were collected by interview with Diabetes in Pregnancy Center staff.

Management of mothers during pregnancy. Antepartum care was provided according to a detailed protocol by a team of diabetologists, obstetricians, neonatologists, nurse educators, dieticians, and social workers. The core of senior physician-investigators remained unchanged throughout the 66-month period of enrollment. All women were seen at the outpatient clinic at least biweekly before 30 weeks' gestation and weekly thereafter. Women with insulin-requiring diabetes were hospitalized for approximately 1 week immediately after enrollment to assess metabolic status and improve diabetes education. A second hospitalization for further improvement of diabetes regulation was instituted at 28 weeks' gestation for women who had enrolled before week 24.

At each outpatient visit and twice weekly during hospitalization, blood samples were drawn after overnight fast to measure plasma glucose[10] and β-hydroxybutyrate levels.[11] Monthly estimates of HbA_{1C} levels were obtained by column chromatography with macrocolumns.[12] Mean values for fasting plasma glucose, β-hydroxybutyrate, and HbA_{1C} during the second and the third trimesters were derived for each subject by averaging all measurements obtained during those intervals. Entry into the program was sufficiently early to secure adequate biochemical documentation of the second trimester in 88% of the women with pregestational diabetes, 53% of the women with gestational diabetes mellitus, and 75% of the women with normal glucoregulation.

Neonatal care. Research personnel attended all deliveries; infants were immediately transferred to Ohio bed warmers and Apgar scores were recorded at 1 and 5 minutes. Umbilical artery pH at delivery was measured in blood drawn from double-clamped segments of umbilical cord. Plasma glucose was determined in cord blood at delivery and in blood samples obtained by heel stick at hourly intervals for the first 4 hours thereafter. Initial feeding was at 4 hours after birth unless hypoglycemia (plasma glucose ≤30 mg/L) was encountered. In that case, infants were fed immediately or intravenous glucose was administered. Determinations of plasma calcium and bilirubin levels and continued assessments of plasma glucose level and vital signs were also obtained. Complete physical examinations and estimations of gestational age as per Dubowitz[13] and Lubchenco[14] were performed by senior neonatologists.

Brazelton neonatal behavioral assessment scale testing. Three of the authors (R. H., P. B., and W. B.) performed all Brazelton neonatal behavioral assessment scale testing. They had been trained to an interrater reliability of >90% at the Brazelton training facility at Children's Hospital in Boston before the inception of the study. Reliability checks were conducted once or twice per year to prevent examiner drift. All 209 infants were examined without knowledge of the mother's metabolic status in a temperature- and light-controlled room near the regular care nurseries. Examinations of preterm infants (i.e., <37 weeks' gestational age) were scheduled at 40 weeks' gestational age to correct for neurobehavior maturation effects. Term infants (37 to 41 weeks) were seen on the second or third day after birth before discharge from the hospital.

Individual Brazelton neonatal behavioral assessment scale responses were categorized into the following four dimensions as per Als, Tronick, Lester, and Brazelton[15]: interactive dimension; motoric dimension; state control dimension; and physiologic control dimension. Descriptions of each dimension and its constituent items are presented in Table I. The interactive, motoric, and state control dimensions were scored 0 = excellent, 1 = average, and 2 = deficient. The physiologic control dimension was scored 0 = average, 1 = deficient.

Statistics. Data were analyzed by the partial correlation, one-way analysis of variance, and multivariate analysis of variance programs provided in the SPSS-X statistical software package[16] χ^2 analyses, and the Fisher exact probability test. Specific group comparisons were

Table I. Brazelton neonatal behavioral assessment scale dimensional analysis*

Dimension	*Assessment*	*Constituent items*
Interactive	Infant's capacity for attention and social responsiveness	Visual and auditory orienting responses, alertness, cuddliness, and consolability
Motoric	Infant's neuromuscular organization and maturity	Motor tone, hand-to-mouth and pull-to-sit abilities, motor maturity, defensive reaction, general activity level, and 21 elicited reflexes
State control	Infant's capacity to control his/her state of consciousness	Habituation to repeated stimuli, peak of excitement, lability of states, rapidity of buildup, irritability, and self-quieting
Physiologic control	Infant's autonomic lability responsiveness	Startle responses, tremulousness, and lability of skin color

made by partitioning 3 × 2 contingency tables as per Castellan[17] within the χ^2 analyses and with Tukey's multiple range test within the analysis of variance and multivariate analysis of variance. Comparisons of partial correlation results were performed according to the procedure of McNemar.[18]

Results

Maternal metabolism during pregnancy. On average, women with pregestational diabetes mellitus were enrolled at 13.2 (SEM = 0.09) weeks' gestation, women with gestational diabetes mellitus at 23.5 (SEM = 0.08) weeks, and nondiabetic study participants at 17.9 (SEM, 1.2 weeks). Values for maternal HbA_{1C}, fasting plasma glucose and β-hydroxybutyrate during the second and third trimesters (mean ± SEM and the range of observed values) for each patient group are summarized in Table II. Multivariate analyses of variance performed on the mean values for each metabolite by patient group (patients with pregestational diabetes mellitus, patients with gestational diabetes mellitus, and nondiabetic patients) and trimester (within subjects factor) showed*: (1) Mean levels of second- and third-trimester fasting plasma glucose and HbA_{1C} were greater in mothers with pregestational diabetes mellitus than those with gestational diabetes mellitus and nondiabetic patients (all $p < 0.05$) and in patients with gestational diabetes mellitus vs nondiabetic patients (all $p < 0.05$); (2) mean second- and third-trimester β-hydroxybutyrate values did not differ significantly between the two diabetic groups; however, both values were significantly higher in mothers with diabetes than in the nondiabetic group ($p < 0.05$); (3) mean fasting plasma glucose values were significantly higher in the second than in the third trimester for both diabetic groups ($p < 0.001$); (4) mean HbA_{1C} was higher in the second than in the third trimester only for the group with pregestational diabetes mellitus ($p < 0.05$); and (5) mean β-hydroxybutyrate was significantly higher in the third than in the second trimester for the group with gestational diabetes mellitus and the nondiabetic group ($p < 0.01$). Before enrollment in our Diabetes in Pregnancy Center, most subjects with pregestational diabetes mellitus were not in optimal control and those with gestational diabetes mellitus were untreated. This most likely accounts for higher mean values of fasting plasma glucose and HbA_{1C} in the second trimester than in the third trimester.

*Since the multivariate analysis of variance is designed to evaluate the effect of trimester on maternal metabolism, subjects missing a second- or third-trimester HbA_{1C}, fasting plasma glucose, or β-hydroxybutyrate value were excluded from the respective analysis. Consequently, the analyses presented here involved 113 of the 185 (61%) gravid women with HbA_{1C} values, 80 of the 127 (63%) gravid women with β-hydroxybutyrate values, and 141 of the 209 (67%) gravid women with fasting plasma glucose values. Analyses of variance performed on the means for each metabolite at each trimester determined that there were no significant differences between gravid patients included in the multivariate analyses of variance (i.e., with metabolic values in both trimesters) and those omitted from these analyses because of missing metabolic data in one of the two trimesters.

Physical findings in newborn. Pertinent neonatal and delivery information is summarized in Table III. One-way analyses of variance were performed on the mean values per patient group for gestational age of delivery, birth weight, and cord glucose. The χ^2 analyses were performed on the incidence of preterm deliveries (gestational age <37 weeks), neonatal macrosomia (birth weight >4000 gm), hypoglycemia, hypocalcemia, hyperbilirubinemia, and 1- and 5-minute Apgar scores <8. Differences in the incidence of neonatal asphyxia (cord pH <7.1) in patients with pregestational diabetes mellitus vs patients with gestational

Fasting plasma glucose (mg/dl)	126 ± 5	70-231	64	104 ± 2	69-150	73
β-hydroxybutyrate (mmol/L)	0.18 ± 0.02	0.02-0.58	29	0.19 ± 0.02	0.06-0.60	34
Gestational diabetes mellitus (n = 112)						
HbA_{1c}	5.2 ± 0.1	3.5-7.8	47	5.2 ± 0.1	3.5-7.4	96
Fasting plasma glucose	104 ± 2	69-153	59	92 ± 1	68-136	112
β-hydroxybutyrate	0.15 ± 0.01	0.07-0.35	37	0.17 ± 0.01	0.03-0.40	72
Nondiabetic (n = 24)						
HbA_{1c}	4.7 ± 0.3	3.3-6.4	17	4.3 ± 0.1	3.3-5.6	22
Fasting plasma glucose	78 ± 1	64-88	18	75 ± 1	62-89	24
β-hydroxybutyrate	0.10 ± 0.01	.04 ± 0.19	16	0.12 ± 0.01	0.05-0.23	21

Mean levels of second- and third-trimester fasting plasma glucose and HbA_{1c} were greater in patients with pregestational diabetes mellitus than those with gestational diabetes mellitus and nondiabetic patients (all $p < 0.05$) and in patients with gestational diabetes mellitus vs nondiabetic patients (all $p < 0.05$). Patients with pregestational diabetes mellitus and gestational diabetes mellitus did not differ significantly in mean second- or third-trimester β-hydroxybutyrate; however, both groups had significantly higher β-hydroxybutyrate values than those of nondiabetic patients at both time points ($p < 0.05$). Mean HbA_{1c} was higher in the second than in the third trimester only for the group with pregestational diabetes mellitus ($p < 0.005$). Mean fasting plasma glucose was higher in the second than in the third trimester for patients with pregestational diabetes mellitus ($p < 0.001$) and gestational diabetes mellitus ($p < 0.001$), but not for nondiabetic patients. Mean β-hydroxybutyrate was higher in the third than in the second trimester for the group with gestational diabetes mellitus ($p < 0.05$) and the nondiabetic ($p < 0.01$) group only.

*Controlling for gestational age at delivery.

was significantly greater in both diabetic groups than in the nondiabetic group (both $p < 0.05$). Whereas the incidence of macrosomia in patients with pregestational diabetes mellitus and patients with gestational diabetes mellitus was twice that in nondiabetic patients, the differences were not statistically different presumably because of the small number of nondiabetic subjects. Mean cord blood glucose levels did not differ significantly among the three groups, nor did the incidence of cord pH <7.1. The incidence of hypoglycemia was significantly increased in the group with pregestational diabetes mellitus compared with the group with gestational diabetes mellitus ($p < 0.01$) and the nondiabetic group ($p < 0.001$), and in the group with gestational diabetes mellitus compared with the nondiabetic group ($p < 0.02$). Finally, there were no significant group differences in the incidence of hypocalcemia, hyperbilirubinemia, or 1-minute Apgar scores <8. Significantly more offspring of patients with pregestational diabetes mellitus (14%) had 5-minute Apgar scores <8 than offspring of the group with gestational diabetes mellitus (2%, $p < 0.001$); whereas the incidence was 5% in the nondiabetic group (p = NS).

Brazelton neonatal behavioral assessment scale evaluations. To determine the relationship between antepartum maternal metabolism and neonate behavior, partial correlations were performed between each of the four Brazelton neonatal behavioral assessment scale dimensions (interactive, motoric, state control, and physiologic control) and the three indexes of maternal metabolism (HbA_{1C}, fasting plasma glucose, β-hydroxybutyrate) after controlling for gestational age at delivery. Partial correlation analyses were instituted because differences in the Brazelton neonatal behavioral assessment scale responses of preterm and term infants have been observed even when the preterm infants were tested at term age.[19]

Results are summarized in Table IV. Significant ($p < 0.05$) or marginally significant ($p < 0.1$) positive correlations were found between antepartum maternal glucoregulation and three of the four Brazelton neonatal behavioral assessment scale dimensions. In each instance, poorer control of maternal glucose was followed by poorer Brazelton neonatal behavioral assessment scale ratings of the neonate. Thus test scores on the interactive dimension were correlated to a marginally significant extent with second-trimester HbA_{1C} ($p < 0.07$) and fasting plasma glucose ($p < 0.06$), and third-trimester HbA_{1C} ($p < 0.06$); the motoric dimension correlated significantly with second- ($p < 0.04$) and third-trimester ($p < 0.02$) HbA_{1C}; and the physiologic control dimension correlated significantly with second-trimester fasting plasma glucose ($p < 0.03$). None of the Brazelton neonatal behavioral assessment scale dimensions correlated significantly with fasting plasma β-hydroxybutyrate.

To evaluate the effects of various perinatal factors on these metabolism-Brazelton neonatal behavioral assessment scale correlations, the partial correlation analyses were repeated with the following variables included as covariates: delivery type (i.e., cesarean vs vaginal), macrosomia, cord glucose, cord pH, neonate hypoglycemia, hyperbilirubinemia, and 1- and 5-minute Apgar scores. Results from these analyses were compared with those reported above via the procedure described by McNemar.[18] In no instance were the previously reported findings altered significantly by any perinatal factor (all $p > 0.70$).

Similarly, we evaluated the effects of ethnicity and socioeconomic status on the metabolism-Brazelton neonatal behavioral assessment scale correlations listed here by repeating the partial correlation analyses with ethnic origin (white vs minority), family income, and mother's and father's highest grade achieved as covariates. As with the perinatal factors, these analyses showed that in no instance were the previously reported findings altered significantly by ethnic or socioeconomic factors (all $p > 0.90$).

To assess for possible interactions linked to the nature of the maternal diabetes, the populations with pregestational diabetes mellitus and gestational diabetes mellitus were analyzed separately. Despite the smaller numbers and metabolic variance in these subgroups similar patterns emerged. As found in the prior analysis with the entire population, scores on the Brazelton neonatal behavioral assessment scale state control dimension did not correlate significantly with any index of antepartum maternal metabolism in the separate groups. And, significant or marginally significant correlations were obtained for the other three Brazelton neonatal behavioral assessment scale dimensions. In gravid women with pregestational diabetes mellitus, second-trimester fasting plasma glucose values correlated with neonate performance on the Brazelton neonatal behavioral assessment scale interactive ($r = 0.24, n = 64, p < 0.06$), motoric ($r = 0.22, n = 64, p < 0.09$), and physiologic control ($r = 0.26, n = 64, p < 0.04$) dimensions; and second-trimester HbA_{1C} correlated significantly with the neonate ratings on the morotic dimension ($r = 0.40, n = 52, p < 0.003$). In gravid patients with gestational diabetes mellitus, second-trimester fasting plasma glucose correlated significantly with neonate performance on the physiologic control dimension ($r = 0.37, n = 59, p < 0.004$); and third-trimester HbA_{1C} correlated significantly with neonate ratings on the motoric dimension ($r = 0.20, n = 96, p < 0.06$).

Comment

The Northwestern University Diabetes Pregnancy Center was established to conduct prospective evaluations of Freinkel's[3] proposition that maternal fuels may exert long-range effects on the progeny by modifying phenotypic gene expression in key cells during critical phases of intrauterine development (i.e., fuel-mediated teratogenesis). This manuscript reports on the observed relations between maternal fasting plasma glucose, HbA_{1C}, and β-hydroxybutyrate in the second and third trimesters and the subsequent behavioral characteristics of 209 singleton neonates. The estimates of fasting plasma glucose and β-hydroxybutyrate levels were obtained at biweekly and weekly intervals to provide indexes of glycemic control and lipid metabolism after 11 to 14 hours of dietary deprivation; the HbA_{1C} measurements were obtained monthly as an index of integrated glycemic excursions during and after meals. Estimation of HbA_{1C} had become clinically feasible at the inception of this study in 1977. Thus HbA_{1C} was chosen as a realistic alternative to random clinic measurements of postprandial plasma glucose because home glucose monitoring had not yet become a standard management procedure. The Brazelton neonatal behavioral assessment scale was chosen to gauge neurobehavior status because it has gained wide acceptance as one of the premier instruments for integrative characterization of nervous system function in the newborn period. Such characterizations may be of particular interest for metabolic correlations with antepartum events inasmuch as substantial central nervous system plasticity still obtains in the neonate and intrinsic function has not been modified by extrauterine environmental factors or interactions with care givers.

We found significant correlations between antepartum maternal glucoregulation and three of the four Brazelton neonatal behavioral assessment scale dimensions. In each case, poorer regulation of maternal glucose was followed by poorer Brazelton neonatal behavioral assessment scale ratings of the neonate. Performance on the motoric dimension correlated with second- and third-trimester HbA_{1C}; performance on the interactive dimension correlated with second- and third-trimester HbA_{1C} and second-trimester fasting plasma glucose; and performance on the physiologic control dimension correlated with second-trimester fasting plasma glucose. It should be noted that these correlations were established within a population of subjects in whom metabolic status was normal to moderately impaired. Thus even in the group with pregestational diabetes mellitus mean values for fasting plasma glucose were <105 mg/dl in the third trimester and did not exceed 231 mg/dl in any study participant. Similarly, mean β-hydroxybutyrate levels in both groups with diabetes were minimally elevated and no single measurement exceeded 0.60 mmol/L. Further, these relations persisted even when the populations with pregestational diabetes mellitus and gestational diabetes mellitus were analyzed separately. Thus insofar as most of the women with pregestational diabetes mellitus had type I diabetes, whereas women with gestational diabetes mellitus are at high risk for later development of type II diabetes, the observed correlations appear to be determined by phenotypic factors (i.e., the degree of the disturbance in the metabolism of the mother during pregnancy) rather than genotypic considerations (i.e., the nature of the mothers' diabetes). Finally, the present results cannot be ascribed to socioeconomic or ethnic variables.

Four additional factors should be considered. First, these findings are consistent with earlier reports that diabetes in the mother may affect neonate Brazelton neonatal behavioral assessment scale responses.[20, 21] However, the present study directly implicates maternal fuels for the first time and provides the additional details concerning temporal relationships, treatment schedules, and neonatal events that can only be gleaned from prospective experimental design. Second, because metabolic control across trimesters may be interrelated we cannot exclude an influence of first-trimester control in our population. Indeed, recent studies by Petersen and colleagues[22, 23] suggest that early (i.e., first trimester) intrauterine growth delay in diabetic pregnancies is associated with psychomotor deficits in the

progeny at age 4 to 5 years. Presumably such delays are derived from mothers with worse diabetic control as judged by earlier evidence that such mothers had worse HbA_{1C}.[24] Third, because glucoregulation is likely to serve as a marker for metabolic control in general, we believe it is premature to identify glucose as the principal factor in these metabolic-behavioral associations.

Finally, we emphasize that the demonstration of these relationships in diabetic patients with good-to-excellent metabolic regulation in the second and third trimesters of gestation attests to the exquisite sensitivity of developmental events to fuel-mediated influences. Given this reduced degree of metabolic variance an attenuation in the magnitude and significance of the obtained correlations was expected. However, the clincial significance of these correlations remains: (1) even relatively slight perturbations in endogenous substances during pregnancy may have deleterious effects on the fetus, and (2) maintaining tight diabetic control during pregnancy has important health benefits to the neonate. The presence of fuel-related neurobehavior deficits in neonates of diabetic mothers with poorer metabolic regulation suggests that such infants start their interactions with care givers from a modified base. Whether these neurobehavior deficits are truly teratogenic (i.e., long-lasting) or transient (i.e., subject to recovery) remains to be established from follow-up studies that are in progress.

A number of colleagues have participated in the establishment of the antepartum and peripartum management procedures at the Northwestern University Diabetes in Pregnancy Center since its inception in 1977. We are particularly grateful to senior collaborators such as Richard L. Phelps in Medicine, Drs. R. Depp, S. Dooley, R. Sabbagha, J. Sciarra, M. Socol, and R. Tamura in Obstetrics, and Drs. J. Boehm and E. Ogata in Neonatology. We are also indebted to the nursing staff of the Clinical Research Unit at Northwestern Memorial Hospital for help in the management of a number of our patients; and to Geoff Page, Ed Murillo, and past members of the Diabetes in Pregnancy Center Biometry section for help in data management and analysis.

"I was devastated when I found out I had genital herpes. What a relief when my doctor recommended a treatment program including Zovirax Ointment."

Zovirax® (acyclovir) Ointment 5% is an ideal complement to any treatment program for initial herpes genitalis. As clinical studies confirm, Zovirax Ointment 5% significantly lessens the duration of pain, shortens viral shedding, *and* speeds healing.[1-3]

Whenever the comfort of a topical antiviral medication is desired, prescribe Zovirax Ointment 5% for initial herpes genitalis. It suits her needs—just when she needs it most.

In initial herpes genitalis,

ZOVIRAX®
(ACYCLOVIR)
OINTMENT 5%
Antiviral Action... Proven Results

Please see brief summary of prescribing information on next page.

ZOVIRAX®
(ACYCLOVIR)
OINTMENT 5%

Before prescribing, please consult full package insert, a summary of which follows:

INDICATIONS AND USAGE: Zovirax (Acyclovir) Ointment 5% is indicated in the management of initial herpes genitalis and in limited nonlife-threatening mucocutaneous Herpes simplex virus infections in immunocompromised patients. In clinical trials of initial herpes genitalis, Zovirax Ointment 5% has shown a decrease in healing time and in some cases a decrease in duration of viral shedding and duration of pain. In studies in immunocompromised patients with mainly herpes labialis, there was a decrease in duration of viral shedding and a slight decrease in duration of pain.

By contrast, in studies of recurrent herpes genitalis and of herpes labialis in nonimmunocompromised patients, there was no evidence of clinical benefit; there was some decrease in duration of viral shedding.

Diagnosis: Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[1] Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases.

CONTRAINDICATIONS: Zovirax Ointment 5% is contraindicated for patients who develop hypersensitivity or chemical intolerance to the components of the formulation.

WARNINGS: Zovirax Ointment 5% is intended for cutaneous use only and should not be used in the eye.

PRECAUTIONS:

General: The recommended dosage, frequency of applications, and length of treatment should not be exceeded (see DOSAGE AND ADMINISTRATION). There exist no data which demonstrate that the use of Zovirax Ointment 5% will either prevent transmission of infection to other persons or prevent recurrent infections when applied in the absence of signs and symptoms. Zovirax Ointment 5% should not be used for the prevention of recurrent HSV infections. Although clinically significant viral resistance associated with the use of Zovirax Ointment 5% has not been observed, this possibility exists.

Drug Interactions: Clinical experience has identified no interactions resulting from topical or systemic administration of other drugs concomitantly with Zovirax Ointment 5%.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg/day given by gavage. These studies showed no statistically significant difference in the incidence of benign and malignant tumors produced in drug-treated as compared to control animals, nor did acyclovir induce the occurrence of tumors earlier in drug-treated animals as compared to controls. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive response for mutagenicity and chromosomal damage occurred, but only at concentrations at least 1000 times the plasma levels achieved in man following topical application.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day or in rats at subcutaneous doses up to 25 mg/kg/day. In rabbits given a high dose of acyclovir (50 mg/kg/day, s.c.), there was a statistically significant decrease in implantation efficiency.

Pregnancy: *Teratogenic Effects*. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c. and i.v.) or in standard tests in the rat (50 mg/kg/day, s.c.). In a non-standard test in rats, fetal abnormalities, such as head and tail anomalies, were observed following subcutaneous administration of acyclovir at very high doses associated with toxicity to the maternal rat. The clinical relevance of these findings is uncertain.[2] There are no adequate and well-controlled studies in pregnant women. Acyclovir should not be used during pregnancy unless the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax is administered to a nursing woman.

ADVERSE REACTIONS: Because ulcerated genital lesions are characteristically tender and sensitive to any contact or manipulation, patients may experience discomfort upon application of ointment. In the controlled clinical trials, mild pain (including transient burning and stinging) was reported by 103 (28.3%) of 364 patients treated with acyclovir and by 115 (31.1%) of 370 patients treated with placebo; treatment was discontinued in 2 of these patients. Other local reactions among acyclovir-treated patients included pruritus in 15 (4.1%), rash in 1 (0.3%) and vulvitis in 1 (0.3%). Among the placebo-treated patients, pruritus was reported by 17 (4.6%) and rash by 1 (0.3%).

In all studies, there was no significant difference between the drug and placebo group in the rate or type of reported adverse reactions nor were there any differences in abnormal clinical laboratory findings.

OVERDOSAGE: Overdosage by topical application of Zovirax Ointment 5% is unlikely because of limited transcutaneous absorption (see Clinical Pharmacology).

DOSAGE AND ADMINISTRATION: Apply sufficient quantity to adequately cover all lesions every 3 hours 6 times per day for 7 days. The dose size per application will vary depending upon the total lesion area but should approximate a one-half inch ribbon of ointment per 4 square inches of surface area. A finger cot or rubber glove should be used when applying Zovirax to prevent autoinoculation of other body sites and transmission of infection to other persons. **Therapy should be initiated as early as possible following onset of signs and symptoms.**

HOW SUPPLIED: Zovirax Ointment 5% is supplied in 15 g tubes (NDC 0081-0993-94) and 3 g tubes (NDC 0081-0993-41). Each gram contains 50 mg acyclovir in a polyethylene glycol base. Store at 15°-25°C (59°-77°F) in a dry place.

Let our eminent medical authorities guide you through major new clinical advances

Introducing the

Year Book of Obstetrics & Gynecology®

This time-saving guide book makes it easy for you to keep current in your field. Each volume represents the year's most significant developments as reported in more than 800 journals and periodicals published worldwide. These selections are condensed to roughly a page in length, so you get all essential facts at a glance.

More importantly, the distinguished physician editors provide thoughtful, probing commentaries that explore the significance of each article while evaluating its practical implications for day-to-day practice.

Editors: Daniel R. Mishell, Jr., M.D.; Thomas H. Kirschbaum, M.D.; and C. Paul Morrow, M.D. **Contributing Editor**: William H. Hindle, M.D.

These books are published annually. For the convenience of its customers, Year Book enters each purchaser as a subscriber to future volumes and sends annual announcements of each volume approximately two months before publication. The new volume will be shipped upon publication unless you complete and return the cancellation notice attached to the announcement and it is received by Year Book within the time indicated (approximately 20 days after your receipt of the announcement). You may cancel your subscription at any time. The new volume may be examined on approval for 30 days and returned for full credit. Year Book will remove your name as a subscriber. Return postage is guaranteed by Year Book to the Postal Service.

A red spot means a lot to a woman.

A red spot may mean breakthrough bleeding.

Tri-Levlen® means a low incidence of breakthrough bleeding/spotting*†

Multicenter study demonstrates significantly less breakthrough bleeding/spotting through the first six cycles[1]

P<0.05 for cycles 1,2,3, and 5[1]

n = number of women with a bleeding event occurring during a cycle.

TRI·LEVLEN®

Levonorgestrel and ethinyl estradiol tablets–Triphasic regimen

may mean a lot to a woman

* Incidence defined as percentage of women with a bleeding event occurring at least once during a pill cycle. Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

† Defined as intermenstrual bleeding.

BERLEX Dedicated to innovation in OB/GYN medicine

TRI-LEVLEN® 28 Levonorgestrel and ethinyl estradiol
TRI-LEVLEN® 21 tablets–Triphasic regimen

BRIEF SUMMARY
Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5) 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted.: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert. 60611-1 5/86

Antenatal microbiologic and maternal risk factors associated with prematurity

James A. McGregor, MDCM,[a] Janice I. French, CNM, MS,[a] Ruth Richter, CNM, MSN,[a] Amalia Franco-Buff, MS,[a] Anne Johnson, MS,[a] Sharon Hillier, PhD,[b] Franklyn N. Judson, MD,[c, d] and James K. Todd, MD[e]

Denver, Colorado, and Seattle, Washington

In a prospective study of 202 women (gestational age 24 ± 4 weeks), we evaluated possible influences of lower genital tract infection or bacterial conditions on obstetric outcomes, including preterm labor, preterm premature rupture of membranes, and preterm birth. The presence of bacterial vaginosis (18.7%) was associated with an increased risk of preterm labor (relative risk, 2.6; 95% confidence interval, 1.08 to 6.46). For women with bacterial vaginosis who also had *Mobiluncus species* morphotypes identified on Gram stain, the relative risk of preterm labor was 3.8 (95% confidence interval, 1.32 to 11.5). Presence of vaginal *Mycoplasma hominis* (10.8% of patients) was associated with both preterm labor (relative risk, 1.8; 95% confidence interval, 0.77 to 4.4) and preterm birth (relative risk, 5.1; 95% confidence interval, 1.45 to 17.9). Recovery of *Staphylococcus aureus* (3.0%) was associated with preterm labor (relative risk, 3.1; 95% confidence interval 1.12 to 8.7). Identification of two or more bacterial-linked abnormalities was also associated with preterm labor (relative risk, 3.3; 95% confidence interval, 1.44 to 7.58). An increased level of vaginal wash protease (≥10 trypsin units) (16%) was associated with preterm labor and was noted in 50% of women with preterm premature rupture of membranes. A history of prior preterm birth was the single best historical predictor of both preterm labor (relative risk, 3.6; 95% confidence interval, 1.92 to 6.83) and preterm birth (relative risk, 6.7; 95% confidence interval, 2.2 to 20.4). History of three or more abortions, antenatal urinary tract infection, and occurrence of medical complications during pregnancy also correlated with increased risk of preterm labor. These findings affirm and refine associations of various maternal reproductive tract infections with preterm labor, premature rupture of membranes, and birth, allowing for controlled treatment trials aimed at prevention of preterm birth. (AM J OBSTET GYNECOL 1990;163:1465-73.)

Key words: Prematurity, preterm birth, bacteria, infection, risks, pathogenesis

Preterm labor with subsequent delivery of premature newborns remains the largest cause of perinatal morbidity and mortality worldwide.[1] Much past work has focused on identification of maternal demographic, behavioral, obstetric, and medical factors associated with increased risk of preterm labor and birth. Disappointingly, interventions on the basis of these risk factors have yielded only inconsistent results.[2-4] To be optimally effective in the reduction of risks of preterm birth, intervention strategies should be based on understanding of the pathophysiologic processes involved and focus on safe treatment of specifically implicated etiologic factors.

Much epidemiologic, clinical, and laboratory information indicates that reproductive tract infection and the inflammatory responses engendered are linked to some instances of preterm labor, preterm rupture of membranes (PROM), and preterm birth.[5-15] Studies have shown that women who have idiopathic preterm labor frequently have one or more of these findings: (1) increased evidence of histologic chorioamnionitis[6, 9]; (2) increased recovery of certain microorganisms from the fetal membranes or placenta[7, 8]; (3) increased recovery of microorganisms, bacterial endotoxin, or inflammatory mediators from amniotic fluid.[8, 10]

Attempts to identify and correlate the presence of specific lower genital tract microflora or bacterial conditions, such as bacterial vaginosis, with preterm birth or PROM have yielded inconclusive findings. A variety of lower reproductive tract microorganisms, including *Neisseria gonorrhoeae, Chlamydia trachomatis, Trichomonas vaginalis,* group B streptococcus, *Mycoplasma hominis,*

Ureaplasma urealyticum, and various anaerobic flora as well as bacterial vaginosis, have been linked to preterm birth in case-controlled studies.[7-9, 11-15] Such studies have been difficult to interpret because: (1) different microorganisms or conditions are sought in various investigations; (2) techniques for screening and identification of microorganisms differ; (3) the prevalence of microorganisms varies in different populations; or (4) associations with multiple microorganisms are not sought. In addition to lower genital tract microflora, the presence of specific cumulative microbial-host interactions that may lead to increased local tissue levels of possible virulence factors, such as phospholipases or proteases, may also play roles in the pathogenesis of preterm labor or PROM.

Therefore we undertook a prospective study to evaluate possible influences of lower reproductive tract microorganisms or bacterial conditions implicated in the occurrence of preterm labor or PROM. Wash samples for measurement of nonspecific vaginal fluid proteases were also evaluated. To increase the applicability of possible results, we used only widely available and relatively inexpensive microbiologic techniques. Detailed aspects of demographic, obstetric, and medical information were collected and correlated with microbiologic findings and reproductive outcomes.

Patients and methods

Patient population. Between January 1985 and April 1986, 202 pregnant women receiving care at two publicly supported prenatal clinics in Denver were enrolled and prospectively followed up with their infants through 6 weeks post partum. Patients were enrolled at approximately 24 weeks' gestation. Women with known multiple gestation, cervical cerclage, placenta previa, history of vaginal bleeding during pregnancy, or history of preterm labor occurring in this pregnancy were excluded. Women were also excluded if within the previous 2 weeks they have received vaginal or systemic antimicrobial treatment, if they reported history of douching within 24 hours of examination, or if they were unwilling or unable to sign informed consent. Six patients were excluded from analysis because they were lost to follow-up for the remainder of the pregnancy or for delivery information. Placenta previa was diagnosed in three women subsequent to enrollment; these women remained in the study. A total of 196 pregnant women and newborns were evaluated. This study was reviewed and approved by the Human Subjects Committee of the University of Colorado Health Sciences Center.

Methods. On admission to the study, patients were interviewed to obtain detailed demographic, obstetric, and medical histories, and to complete the Creasy risk of preterm delivery scale.[2] A sterile speculum examination was performed; characteristics of vaginal discharge (consistency, amount, color, odor) were recorded on standard forms. Sterile cotton swabs that had been previously demonstrated nontoxic for chlamydial and *Mycoplasma* cultures were used to collect specimens. Samples obtained were endocervical specimens for culture of *N. gonorrhoeae, C. trachomatis,* and Microtrak (Syva Corp., Palo Alto, Calif.) chlamydia antigen, and midvaginal cotton swab cultures for *M. hominis, U. urealyticum,* group A streptococcus, group B streptococcus, *Staphylococcus aureus, Gardnerella vaginalis,* and yeast species. Because of new information during the course of the study, a vaginal smear for Gram stain evaluation of bacterial vaginosis and *Mobiluncus species* morphotypes and vaginal fluid pH were added to the test procedures. Vaginal fluid pH was assessed with Nitrazine (E. R. Squibb and Sons, Inc., Princeton, N. J.) paper and recorded as >4.5 or ≤ 4.5. One milliliter of saline solution was inoculated with a cotton swab saturated with vaginal fluid and was examined microscopically for *Trichomonas vaginalis* and yeast, and a standardized, semiquantitative assessment of vaginal leukocytes and bacteria was carried out. A drop of vaginal fluid was combined with a drop of 10% potassium hydroxide to test for release of amine odor and for further microscopic examination for yeast pseudohyphae. Finally, the posterior vaginal fornix was irrigated with 5 ml of sterile Dulbecco's phosphate buffered saline solution and, after standardized mixing, aspirated into a sterile syringe. These vaginal wash specimens were frozen immediately at $-20°$ C and then frozen at $-70°$ C within 4 hours of collection.

Culture specimens were immediately inoculated on standard, easily available media in the examination room. Endocervical cotton swabs were inoculated onto chocolate agar and modified Thayer-Martin medium split plates and held in a carbon dioxide environment for the recovery of *N. gonorrhoeae.* A separate endocervical swab was inoculated into sucrose-phosphate glutamate transport media for recovery of *C. trachomatis.* Additional cervicovaginal swabs were inoculated onto 5% sheep's blood agar (tryptic soy base, Remel, Denver, Colo.) for identification of group A streptococcus, group B streptococcus, *S. aureus, G. vaginalis,* and yeast, and into a standard mycoplasma medium for recovery of *M. hominis,* and *U. urealyticum.* Specimens were held at 4° C or at room temperature as appropriate and were transported to the laboratory within 4 hours of collection. Evaluation for *T. vaginalis,* yeast pseudohyphae, and amine odor were performed in the clinic setting. The remainder of the saline solution preparation was held at 4° C and evaluated microscopically for leukocytes and bacteria semiquantitatively in the laboratory. In addition, the saline solution wet preparation was semiquantitatively tested for nonspecific protease activity using the Azocoll substrate.[16] Cultures for *C. trachomatis, M. hominis,* and *U. urealyti-*

cum specimens were frozen at −70° C and processed in batches.

Standard techniques were used for culture of *C. trachomatis.*[17] After 48 hours incubation at 35° C, inoculated cycloheximide-treated McCoy cell monolayers were treated with fluorescence-conjugated antichlamydia monoclonal antibody (Microtrak, Syva Corp.) and examined microscopically for the presence of stained inclusions. Negative cultures were blind passaged once and reprocessed. Chlamydia antigen preparations were processed as recommended by the manufacturer. *M. hominis* and *U. urealyticum* were cultured and identified with the Mycotrim GU triphasic culture system (HANA Biologics, Inc., Alameda, Calif.). *G. vaginalis* were recovered by reincubating the chocolate–Thayer-Martin agar plate anaerobically for 3 days after examination for *N. gonorrhoeae.* Microorganisms were identified with standard techniques.[17]

Gram stain evaluation for bacterial vaginosis and *Mobiluncus species* morphotypes was performed using the method and criteria of Spiegel et al.[18] Gram stains were evaluated by one of the investigators (S. H.) who remained blinded to patient symptoms, findings, and outcomes.

After enrollment, patients continued routine prenatal care. None of the patients was seen in special clinics for preterm birth prevention and microbiologic evaluations were not repeated as part of the study protocol. Microbiologic findings were not known to the patients' health care providers. A single patient from whom *N. gonorrhoeae* was recovered was treated with a standard oral therapy specific for this infection. After birth and completion of the 6 weeks follow-up, maternal and newborn medical records were reviewed to obtain information on pregnancy and newborn course. If records were unavailable, the data were obtained by telephone calls and written correspondence to private physicians and patients.

Patients were considered to have preterm labor if the medical records reported hospital evaluation for regular uterine contractions before 37 weeks' gestation for which patients received treatment (e.g., parenteral or oral tocolytic treatment or intravenous hydration and bed rest, or contractions that resulted in preterm birth). Preterm birth was defined as birth before completion of 37 weeks' gestation. Gestational age was determined by overall "best" obstetric criteria that included history of last menstrual period, clinical dating criteria (uterine size at first examination, gestational age at detection of fetal heart rate by fetoscope, growth of fundal height), and ultrasonographic measurements, as well as newborn examination.[19] Determination of gestational age was performed in a blinded fashion before correlation with any other study determination. Preterm premature rupture of membranes was defined as rupture of fetal membranes before 37 weeks' gestation and >1 hour before the onset of labor.

Data were analyzed with two-tailed χ^2 or Fisher's exact tests for nonparametric data and the Student's *t* test for normally distributed parametric data. Relative risks (RR) and 95% confidence intervals (CI) were also calculated with SPSS (SPSS Inc., Chicago). Variables associated with preterm birth with univariate analysis or those that had been frequently associated with preterm birth in other studies were included in a logistic regression model.

Results

The majority (143) of participants were of northern European ancestry (70.8%), 21 (10.4%) were black, 32 (15.8%) were Hispanic, and 6 (3%) were of Native American or Asian descent. The mean maternal age was 23.5 ± 4.7 years (Table I). A total of 42% were nulliparous and 67% were married; all were of low socioeconomic status attending publicly supported clinics. The mean gestational age at enrollment was 24.2 ± 4.7 (SD) weeks. Preterm labor occurred among 33 (16.8%) of the patients. Twenty (60.6%) of these patients received parenteral tocolytic therapy for preterm labor. The mean gestational age at diagnosis of preterm labor was 29.2 ± 5.3 weeks. Nine patients (4.5%) were delivered of preterm infants (≤36 weeks) at a mean gestational age of 35.4 ± 0.7 weeks. Preterm PROM occurred among four (2.1%) study patients. One of the three women with placenta previa detected after study enrollment was seen for preterm labor and she was treated with intravenous hydration and bed rest only; all three women with placenta previa were delivered of infants at term. Preterm labor or delivery did not occur in any of the six (3.1%) patients in whom pregnancy-induced hypertension developed, the two patients who had abruptio placentae, or the two who were treated for clinical chorioamnionitis. There were no perinatal or neonatal deaths. Three infants were born with minor congenital anomalies. Seven infants (3.6%) were small for gestational age and 30 (16.8%) were large for gestational age.

The women in whom preterm labor or preterm rupture of membranes developed or who were delivered of preterm infants and those who did not suffer these complications did not differ in any demographic or behavioral factor except for reported use of recreational "street drugs" (Table I). These women were significantly less likely to suffer preterm labor or delivery. Marijuana was the most common recreational drug; one patient reported additional use of both methamphetamine and cocaine.

Several medical, obstetric, historical, and antenatal factors were associated with the occurrence of preterm labor or birth (Table II). History of prior preterm birth

was the single best historical predictor of both preterm labor (RR, 3.6; 95% CI, 1.92 to 6.83) and preterm birth (RR, 6.7; 95% CI, 2.2 to 20.4). A Creasy risk index score of ≥10 was significantly associated with development of preterm labor ($p < 0.05$; RR, 2.28; 95% CI, 1.22 to 4.29). The RR of preterm labor for women with any medical problem was 2.4 (95% CI, 1.25 to 4.64). Medical problems experienced by the women in this sample included asthma requiring medication, prior pyelonephritis or frequent urinary tract infections, chronic hypertension, mitral valve stenosis, class III heart disease, and gestational diabetes. Women with three or more abortions (spontaneous or elective) had a RR of preterm labor of 2.9 (95% CI, 1.34 to 6.25). History of prior preterm birth, increased Creasy risk index, or medical problems was not associated with any microbiologic finding.

Recovery rates for microbiologic samples are shown in Table III along with microorganisms associated with preterm labor and delivery. As noted, the patient from whom *N. gonorrhoeae* was recovered received single-dose antibiotic treatment. *M. hominis* was recovered in 10.8% of patients, and was significantly associated with premature delivery ($p < 0.05$; RR, 5.1; 95% CI, 1.45 to 17.9). *U. urealyticum* was recovered from 64% of study women and was not significantly associated with preterm labor or delivery. Two (15.4%) of the *C. trachomatis* culture-positive women were delivered of preterm infants compared with seven (3.8%) of the chlamydia culture-negative women ($p = 0.09$; RR, 4.0; 95% CI, 0.97 to 16.7). Semiquantitative examination for vaginal white blood cells or bacteria did not correlate with obstetric outcomes.

Gram stain evaluation of vaginal fluid detected bacterial vaginosis among 18.7% (26) of the evaluated patients ($N = 139$). *Mobiluncus species* morphotypes were identified among eight (30.8%) of these women with bacterial vaginosis or 5.8% of those examined. Bacterial

Table III. Association between recovered microorganisms and preterm labor and preterm birth

vaginosis was detected among 35% of these Gram stain–evaluated women who had preterm labor as compared with 14.5% of the women who did not have preterm labor. The RR of preterm labor for women with bacterial vaginosis was 2.6 (95% CI, 1.08 to 6.46). For those women with bacterial vaginosis who also had *Mobiluncus species* morphotypes present, the RR for preterm labor was 3.8 (95% CI, 1.32 to 11.5).

S. aureus was identified among six (3.0%) patients. Preterm labor occurred in three of these women ($p = 0.06$; RR, 3.1; 95% CI, 1.12 to 8.7). Group B streptococcus was recovered from seven (3.5%) of the women and was not associated with preterm labor or preterm delivery. Three of these women had group B streptococcus identified independently by their care providers, and received treatment.

Approximately 29% (28.6%) of study participants had two or more of the microorganisms or conditions sought in this study. Identification of two or more positive cervicovaginal isolates or conditions was associated with increased risk of preterm labor (RR, 3.3; CI, 1.44 to 7.58). As would be expected, bacterial vaginosis was significantly associated with detection of *Mobiluncus species* morphotypes, *G. vaginalis,* and *M. hominis* ($p < 0.05$). Although frequently recovered, *U. urealyticum* was not statistically associated with other microbiologic findings. Recovery of group B streptococcus and *S. aureus* were also not statistically associated with other microbiologic findings; however, the numbers are small. Neither *T. vaginalis* nor group A streptococcal infection was identified with these methods.

Vaginal wash nonspecific protease levels ≥10 trypsin units/ml were detected in 32/196 (16%) of the women. Increased vaginal protease activity was noted among two of four (50%) women who had preterm PROM. Overall, findings of ≥10 trypsin units/ml were not associated with increased risk of preterm birth. Among the 47 women tested, Nitrazine paper determination of vaginal pH >4.5 or ≤4.5 was not associated with abnormal outcome.

Recovery of *M. hominis* was more common among nonwhite participants (18.2%) than among white participants (7.4%) ($p < 0.05$). Other associations between ethnicity and microorganisms recovered were not identified. Detection of bacterial vaginosis, *Mobiluncus species, M. hominis,* and *C. trachomatis* occurred more often among unmarried women ($p < 0.1$).

Fully 48% of the study patients received some form of antimicrobial therapy during their antenatal care. Twenty-eight (14.2%) were treated for a single urinary tract infection. Women who had one or two urinary tract infections had a higher incidence of preterm labor ($p < 0.06$; RR, 1.98; 95% CI, 0.97 to 4.04). These women were asymptomatic and had negative test of cure urine cultures after treatment. Women who had more than two lower urinary tract infections ($n = 4$) or pyelonephritis ($n = 3$) received oral antibiotic treatment daily until delivery and did not have preterm labor or birth. Review of antenatal records revealed that 36 (18.3%) study patients were treated for yeast vaginitis; and 18.8% received treatment of vaginitis other than yeast. Two (1%) patients were treated for *N. gonorrhoeae* (a further patient received single-dose treatment after enrollment), 5.1% for *T. vaginalis,* 9.6% for *G. vaginalis,* 4.6% for cervicitis, 0.5% for *C. trachomatis,* and 2% for group B streptococcus. Preterm labor occurred more often among women who received treatment of *Gardnerella vaginalis*–associated vaginitis ($p < 0.05$) from their clinical care providers. Nevertheless, fully 82% (27/33) of the women who had pre-

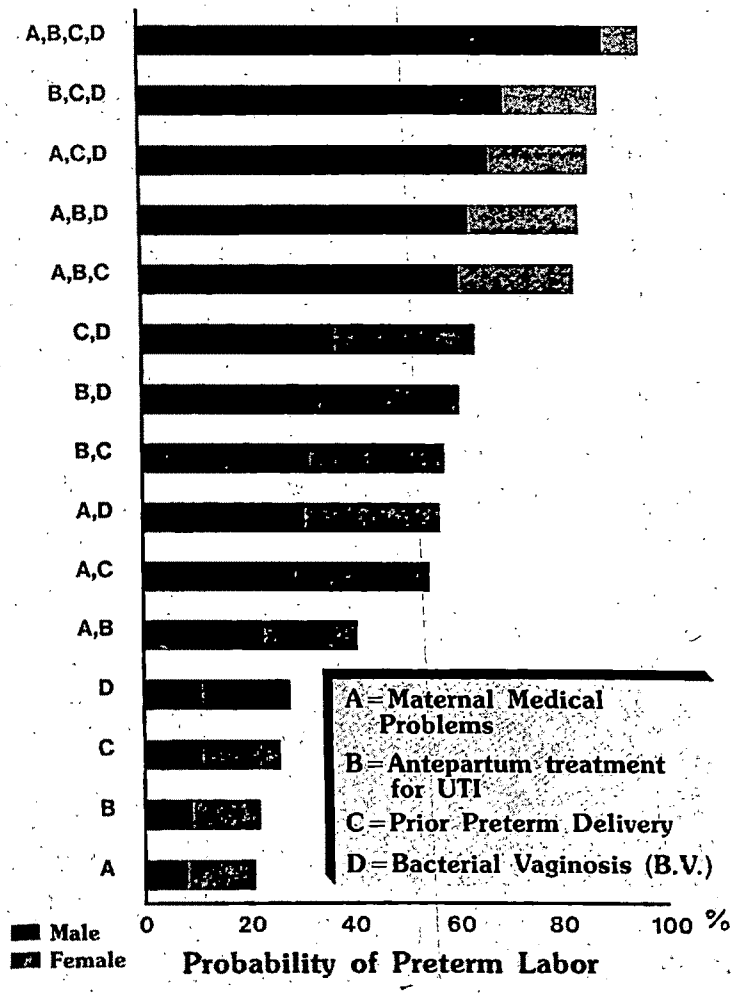

Fig. 1. Logistic regression analysis: Probability of preterm labor in presence of selected factors. (*UTI*, Urinary tract infection.)

term labor did not receive antimicrobials before the diagnosis.

To evaluate possible independent effects of several maternal historical factors and the presence of different microorganisms and conditions on the occurrence of preterm labor a logistic regression model was constructed. Maternal historical and microbiologic variables that approached significance ($p \leq 0.1$) with univariate analysis in this study or in past studies were incorporated into the model. Variables tested in the model were maternal medical problems, history of three or more abortions, maternal age, fetal gender, Creasy risk score, antepartum treatment for urinary tract infection, antepartum treatment with nontopical antimicrobial agents, recovery of *S. aureus, G. vaginalis, M. hominis, Mobiluncus species,* and the presence of bacterial vaginosis. Four factors remained in the model and were significantly related to development of preterm labor: prior preterm birth, maternal medical problems, antepartum treatment for urinary tract infection, and bacterial vaginosis (Fig. 1). In this cohort, women carrying female fetuses appeared to have increased risk of preterm labor compared with women carrying male fetuses. Among the single risk factors, the probability of preterm labor was highest for those women with bacterial vaginosis (males: RR, 4.6; females: RR, 11.3). Probability of preterm labor increased additively as more risk factors were included (Fig. 1). Calculations of RR, attributable risk and population-attributable risk for factors associated with preterm labor and birth (RR, ≥2.0; CI, not including 1.0) are shown in Table IV.

Comment

The incidence (4.5%) of preterm birth within this sample is lower than the 6% to 10% incidence usually observed in studies of similar U.S. populations.[3] This study's exclusion criteria, specific definition of preterm birth, and a possible unidentified selection bias may account for this relatively low occurrence of preterm birth. The low number (2%) of women in this study who had preterm PROM is consistent with similar populations.[3] Rates of recovery of lower reproductive tract

Table IV. Relative risk and attributable risk for factors associated* with preterm labor and preterm delivery

Pregnancy outcome	*Significant associations*	*Relative risk*	*Attributable risk*	*Population attributable risk (%)*
Preterm labor	Microbiologic associations

microorganisms and recognition of bacterial vaginosis in this study are also consistent with findings in similar populations. Because of the relatively small number of women who had adverse outcomes and the large number of study factors analyzed, individual associations should be considered cautiously with confirmation sought in other studies.

Our findings support possible roles for bacterial vaginosis and associated microorganisms (i.e., *Mycoplasma hominis*) in preterm labor and birth. Past work is somewhat difficult to compare, principally because of differing criteria used for identification of bacterial vaginosis. Minkoff et al.[12] found an insignificant association between nonspecific vaginitis and preterm birth with a diagnosis based on presence of two of three clinical criteria. Subsequently, several investigators noted that clinical interpretation of vaginal findings for bacterial vaginosis is unreliable during pregnancy.[13, 20] In Minkoff's study,[12] *Bacteroides species* were the only identified microorganisms associated with increased incidence of preterm rupture of membranes and preterm birth among inner-city women. *Bacteroides species* are among the predominant anaerobic bacteria recovered from women with bacterial vaginosis.

In a case-controlled study comparing women in preterm labor and uncomplicated pregnancies, Gravett et al.[8] detected vaginal wash gas-liquid chromatographic profiles consistent with bacterial vaginosis significantly more often among the women with preterm labor. Subsequent work by these investigators with either gas-liquid chromatography or Gram stain to detect bacterial vaginosis further supports associations between bacterial vaginosis and preterm labor, preterm PROM, and amniotic fluid infection.[9, 13, 15]

As used here, vaginal Gram stain criteria have been shown to be reliable between trained observers and to more accurately predict positive clinical findings of bacterial vaginosis than either gas-liquid chromatography or vaginal culture for *G. vaginalis*.[20] Vaginal culture for *G. vaginalis*, even when done semiquantitatively, has been shown to be sensitive but nonspecific for detection of bacterial vaginosis.[20] *G. vaginalis* has been recovered from up to 80% of women without clinical evidence of bacterial vaginosis.[8] Therefore, it is not surprising that recovery of *G. vaginalis* in the present study was not associated with preterm labor or birth. Similarly, Gravett et al.[8] reported equivalent recovery rates for vaginal *G. vaginalis* among women admitted in preterm labor and matched control women with uncomplicated pregnancies.

The role of genital mycoplasmas in preterm birth remains controversial. This study confirms the work of others showing that antenatal isolation of *U. urealyticum* from either the vagina or endocervix is not associated with increased risk of prematurity.[11, 14, 30] In this study, 75% of the women who had preterm labor and 61% of those who did not experience preterm labor demonstrated vaginal *U. urealyticum*. In contrast, *U. urealyticum* recovered from between leaves of the amniochorion has been associated with histologic chorioamnionitis and preterm birth in several studies, including a well designed case-controlled study that statistically controlled for confounding obstetric factors.[7, 9] McCormack et al.[21] reported increased birth weight among *U. urealyticum*–colonized women who received antenatal erythromycin treatment in a double-blind placebo-controlled treatment trial investigating the role of genital mycoplasmas in pregnancy. This occurred even though treated women remained colonized. McCormack hypothesized that erythromycin treatment aids in prevention of upper genital tract colonization or infection with *U. urealyticum* during late gestation. However, the presence of other erythromycin-susceptible microorganisms such as

C. trachomatis, group B streptococcus, some *M. hominis* strains and anaerobes were not evaluated. Further, gestational length was not reported.

Although presence of *M. hominis* has been linked to prematurity and low birth weight, more recent work that controls for the presence of other bacteria or bacterial conditions has not consistently found *M. hominis* to be a significant risk factor for prematurity.[11, 12, 14] In this study, recovery of *M. hominis* was significantly associated with preterm birth. However, *M. hominis* was also significantly associated with the identification of bacterial vaginosis and *C. trachomatis*. *M. hominis* was not retained as an independent risk factor in our multivariate model for preterm labor.

C. trachomatis, group B streptococcus, and *S. aureus* were recovered from smaller numbers of the women in this study. *C. trachomatis* has been associated with increased risk of preterm birth when serologic evidence of recent or more extensive infection (immunoglobulin M) is present.[11, 14] Although serologic testing was not performed in this study, antenatal recovery of *C. trachomatis* in small numbers of patients (6.5%) was associated with increased risk ($p = 0.09$; RR, 4; 95% CI, 0.97 to 16.66) of preterm birth. Identification of group B steptococcus (3.5%) was not associated with poor obstetric or perinatal outcome, possibly due in part to the small number of women studied as well as antenatal and intrapartum treatment given to some culture-positive women. Although not commonly sought in women at risk of preterm birth, *S. aureus* has been recovered from the vagina in up to 5% of pregnant women.[22] We noted *S. aureus* in 3% of women sampled, with preterm labor occurring in half of these women (Table II).

The role of urinary tract infection and asymptomatic bacteriuria in preterm birth remains unclear.[23] Studies appear divided as to those that show a positive association between urinary tract infection and preterm birth and those that show no association. Both univariate and multiple regression analysis of our findings support antenatal urinary tract infection as a risk factor for preterm labor. That this effect occurs despite clinically adequate treatment suggests the presence of unrecognized associated factors or that urinary tract infection exerts a sustained deleterious effect.

Similar to the findings of Main et al.,[3] use of the standardized Creasy risk index for preterm birth in this population of poor women was not clinically useful in predicting those at risk. Fully 43% of women tested were designated as high risk for preterm birth by this tool; preterm labor actually developed in only 24% of these women and 7% were delivered of preterm infants. Indeed, one component of this scale, prior preterm birth, was a more accurate predictor of preterm labor than the overall risk index score.

Increased concentration of vaginal wash protease (≥10 trypsin units) was associated with increased risk of PROM. The association of increased vaginal wash protease activity with subsequent preterm rupture of membranes suggests that the presence of protease-releasing vaginal microorganisms or inflammatory responses to infection may lead to fetal membrane damage by spread through the cervix. Both bacteria and inflammatory cells can release proteolytic enzymes, including collagenases, which may weaken fetal membranes.[16, 24] Inflammatory mediators, including interleukin-1 and tumor necrosis factor, may initiate or potentiate these or other processes leading to preterm birth. Concentration of proteases and phospholipases and other factors are suggested as possible virulence factors for preterm birth and may originate from the cumulative presence of genital microorganisms and the host responses they engender.

Table IV shows calculated relative risks, attributable risks, and population-attributable risks for factors associated with preterm labor and preterm delivery. The presence of *S. aureus* in the mother's vagina was associated with greatest attributable risk of preterm labor. Inasmuch as recovery of *S. aureus* was uncommon (3%), the population-attributable risk was only 5.9%. Bacterial vaginosis was more common (18.7%) and associated with 23.0% population-attributable risk of preterm labor. Findings of *Mobiluncus species* morphotypes are also associated with a high calculated attributable risk of preterm labor. Whereas the presence of *Mobiluncus species* may constitute a separate risk factor, identification of mobiluncus may reflect increased severity of bacterial vaginosis.

History of either prior maternal preterm birth or ≥three abortions (spontaneous or induced) was also associated with increased attributable risk and population-attributable risk of preterm labor (Table IV). Prior preterm birth, but not prior abortion, has been consistently linked with subsequent preterm labor and birth in past studies.[4] Factors that account for increased risk of repeated preterm births remain unknown but could include ongoing subclinical endometrial infection, as suggested by Toth et al.[22] or some other persisting biologic predisposition.

Presence of *Mycoplasma hominis* was associated with 30% population-attributable risk of preterm birth. Again, whereas the presence of *M. hominis* might mediate specific risks of preterm birth, this microorganism occurred most commonly in the presence of bacterial vaginosis.

Interestingly, the presence of two or more microbial

infections or conditions was associated with significant risk of preterm birth (RR, 6.9; population-attributable risk, 71%). This suggests that whereas an individual infection or microbial condition may not have been powerful or frequent enough to be consistently associated with preterm labor or birth in this cohort, combinations of individual microbial conditions may contribute to a significant number of preterm births. Similarly, multivariate analysis (Fig. 1) suggests cumulative interactions occurring between presumably noninfection related factors, such as medical problems, and prior preterm birth with bacterial vaginosis.

Findings of this prospective study show that common and readily identifiable genital tract microbial infections or conditions are significantly associated with increased risks of preterm labor and birth. Whether selective treatment of one or more of these infections or conditions can effectively reduce occurrences of preterm birth is the subject of ongoing investigations.

The relationship between plasma estradiol and the increase in bone density in postmenopausal women after treatment with subcutaneous hormone implants

J. Studd,[a] M. Savvas,[a] N. Waston,[a] T. Garnett,[a] I. Fogelman,[b] and D. Cooper[c]
London, England

Twenty-three postmenopausal women with a median of 2 years past menopause (range, 1 to 12 years) and a median age of 52 years (range, 39 to 62 years) were recruited to participate in a longitudinal study designed to investigate the factors that influence the increase in bone density with subcutaneous estradiol and testosterone implants. All women received 75 mg of estradiol with 100 mg testosterone subcutaneously. Bone density was measured at the spine and hip by dual-photon absorptiometry before therapy and after 1 year of subcutaneous hormonal therapy. The mean pretreatment bone density at the lumber vertebrae and neck of the femur was 0.84 grams of hydroxyapatite per square centimer (SD, 0.11) and 0.73 grams of hydroxyapatite per square centimeter (SD, 0.10), respectively. The bone density at both sites increased with values of 0.91 grams of hydroxyapatite per square centimeter (SD, 0.11) and 0.75 grams of hydroxyapatite per square centimeter (SD, 0.11), respectively. These values represent an increase of 8.3% ($p < 0.0001$) at the spine and 2.8% ($p < 0.01$) at the neck of the femur. The plasma estradiol level increased from a median of 80.5 pmol/L to 453 pmol/L ($p < 0.001$). The percentage increase of vertebral bone density was not related to age, number of years past the menopause, pretreatment bone density, or serum testosterone levels, but a significant correlation was found between the percentage increase in bone density at the spine and the serum estradiol level ($p < 0.02$, $r = 0.45$). (AM J OBSTET GYNECOL 1990;163:1474-9.)

Key words: Osteoporosis, menopause, estradiol

After Albright's[1] observation that estrogen therapy can reduce urinary calcium excretion in postmenopausal women a number of prospective studies confirmed the values of estrogen replacement therapy in the prevention of postmenopausal osteoporosis.[2-4] Epidemiologic studies[5, 6] also showed a reduction in the incidence of osteoporotic fractures with such therapy.

Most studies used oral estrogen therapy, which although effective in the suppression of climacteric symptoms usually results in plasma estradiol and follicle-stimulating hormone (FSH) levels that are still in the postmenopausal range.[7] Although it has been claimed that the minimum dose of oral estrogen required to prevent postmenopausal osteoporosis is 0.625 mg conjugated equine estrogen[8] the optimal dose and route of estrogen necessary to achieve an increase in bone density is not known.

The percutaneous route of administration avoids the enterohepatic circulation and is associated with physiologic plasma levels of estradiol and estrone. This is in contrast to the low levels of estradiol and high levels of estrone found after oral therapy with both conjugated equine estrogens or estradiol valerate.[9, 10] Subcutaneous implants of estradiol and testosterone are effective in the alleviation of climacteric symptoms,[11] and a cross-sectional study[12] showed an apparent superiority of implant therapy over oral therapy in the therapeutic effect on bone density. The suggestion was made in this study that the greater bone density after implant therapy was a result of the greater plasma estradiol levels achieved with this route when compared with oral estrogen therapy.

We present the results of a prospective study of estradiol and testosterone implants on the bone density and plasma hormone levels in postmenopausal women over 1 year of therapy.

Patients and methods

A total of 23 postmenopausal women with a median age of 52 years (range, 39 to 62) were recruited into

§$p < 0.01$, Wilcoxon matched-pair signed-rank test.

this prospective study. The median number of years past the menopause was 2 (range, 1 to 12). Menopausal status was defined as amenorrhea >1 year's duration with a serum FSH level >20 IU/L.

All women received hormone replacement therapy by subcutaneous implants of 75 mg estradiol and 100 mg testosterone. A further implant of the same dose of estradiol and testosterone was given after 6 months and again at 1 year.

Assays of FSH, estradiol, and testosterone were performed before treatment and at 1 year. The bone density was estimated in the spine of L2-4 and in the neck of the right femur with a Novo 22A BMC-LAB with gadolinium 153 as the source of radiation. The absorptiometer was standardized with a solution radiologically equivalent to hydroxyapatite, and the results were expressed as grams of hydroxyapatite per unit projected area of bone in square centimeters (gHa/cm²). The precision of the machine with the use of the phantom was 0.69% and short-term precision for normal subjects was 2.04%. Measurements were made before insertion of the hormone implant and at 12 months after therapy within 1 week of the insertion of the third implant.

Statistical analysis. The bone density values before and after treatment approximated to a normal distribution and the increase was therefore analyzed with the paired Student t test. The hormonal parameters could not be regarded as normally distributed and the changes were analyzed with the Wilcoxon matched-pairs signed-rank test. The Spearman correlation coefficient was calculated to express the relationship between the changes in bone density and the serum estradiol levels, serum testosterone levels, age, number of years past the menopause, and pretreatment bone density.

Results

Of the 23 patients studied 22 patients showed an increase in the bone density after 1 year of therapy (Table I). The mean bone density at the lumbar spine before therapy was 0.84 gHA/cm² (SD 0.11), which increased to 0.91 gHA/cm² (SD, 0.11) after 1 year ($p < 0.0001$). The value for the proximal femur was 0.73 gHA/cm² (SD, 0.10), which increased to 0.75 gHA/cm² (SD, 0.11, $p < 0.01$). The mean increase in the lumbar spine was 0.07 gHa/cm² (95% confidence interval, 0.06 to 0.08 gHa/cm²). The mean increase at the femur was 0.02 gHa/cm² (95% confidence interval, 0.01 to 0.04 gHa/cm²). These values represent a mean increase in the bone density of 8.3% at the spine and 2.8% at the neck of the femur after 1 year.

The median serum FSH level before therapy was 71 IU/L (range, 28 to 100 IU/L) with a median serum estradiol level of 80.5 pmol/L (range, 30 to 580 pmol/L) and a serum testosterone level of 0.6 nmol/L (range, 0.3 to 1.8). After 1 year of therapy the serum FSH level significantly reduced to 12 IU/L (range, 1 to 62; $p < 0.001$), the serum estradiol level increased to 453 pmol/L (range, 204 to 883; $p < 0.001$), and the serum testosterone level increased to 0.9 nmol/L (range, 0.4 to 2.4; $p < 0.01$).

A significant correlation was found between the percentage increase of vertebral bone density and the

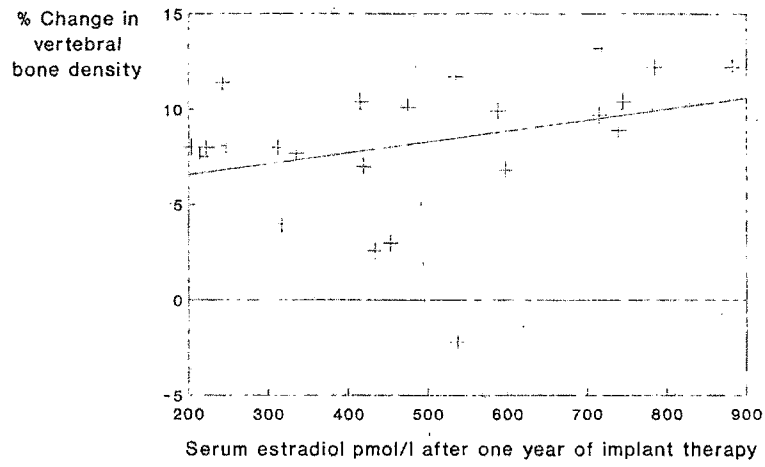

Fig. 1. Correlation between percentage increase in vertebral bone density with plasma estradiol levels after 1 year of therapy with estradiol and testosterone implants.

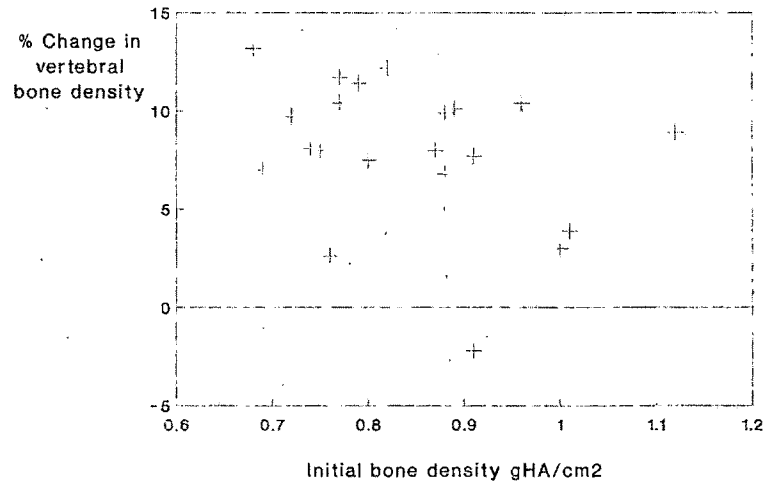

Fig. 2. Effect of pretreatment bone density on percentage increase in bone density with estradiol and testosterone implants.

plasma estradiol levels achieved after 1 year of therapy(Fig. 1, $r = 0.45$; $p < 0.02$). There was no significant correlation between the increase in bone density and the initial bone density (Fig. 2), age (Fig. 3), the number of years past the menopause (Fig. 4), and the serum testosterone level (Fig. 5).

Comment

These data show an increase of 8.3% in the bone density at the spine and 2.8% at the hip after 1 year of therapy with subcutaneous estradiol and testosterone implants. Evidence from our cross-sectional study with the use of the same method of bone densitometry reporting the vertebral bone density of 1.02 gHa/cm^2 and proximal femur values of 0.80 gHa/cm^2 after 8 years of such therapy[12] strongly suggest that this increase is not transient and will be maintained over the years.

Christiansen et al.[13] reported that the use of a combined preparation of oral estradiol, estriol, and norethindrone within 3 years of menopause resulted in an increase in bone density of 3% after 3 years of therapy. Lindsay et al.[14] (1984) found an increase of 2% to 4% over 5 years when mestranol 25 μg was prescribed within 3 years of menopause but this dose only maintained bone density if it was started more than 3 years after menopause. More recently Munk-Jensen et al.[15] reported an increase of 6.4% in the vertebral bone density of women treated within 2 years of menopause with continuous oral estradiol and norethindrone for 1 year. None of these authors reported the estradiol levels obtained with the therapy. In our study we were able to show an increase in bone mass even 10 years after menopause. This increase was the same as found in the younger postmenopausal woman and was also inde-

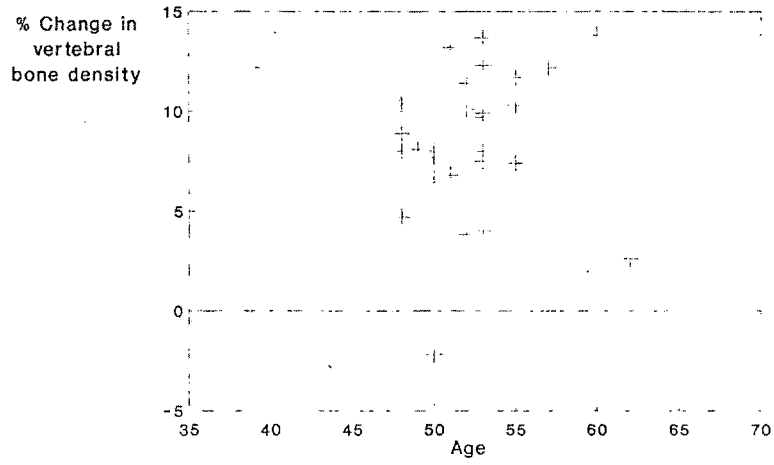

Fig. 3. Effect of age on percentage increase in bone density with estradiol and testosterone implants.

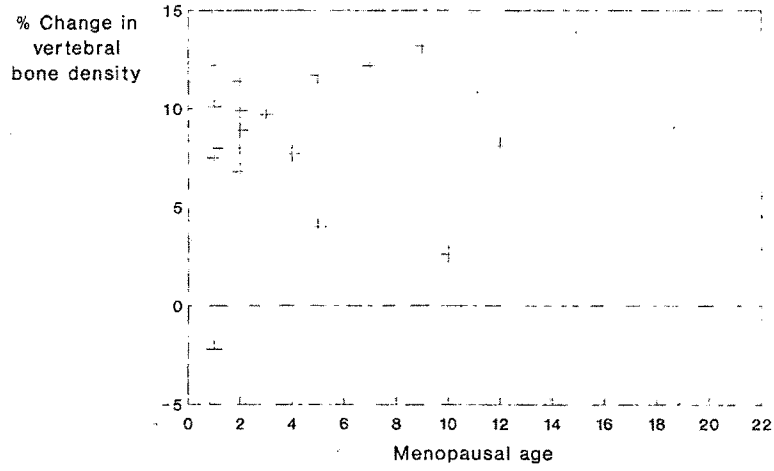

Fig. 4. Effect of number of years past menopause on percentage increase in bone density with estradiol and testosterone implants.

pendent of the initial bone density. The correlation between the percentage increase in bone density and the serum estradiol levels supports the hypothesis that the greater effectiveness of this mode of therapy may be a result of the higher serum estradiol levels achieved. Oral estrogen therapy is associated with lower estradiol levels and a less good skeletal response.[12]

The importance of the testosterone component of the treatment is unknown but there was no correlation in this study between plasma testosterone levels and the increase in bone density. Barlow et al.[16] could not show that the addition of testosterone to estrogen therapy improved bone density. However there is some evidence that adrenal androgens may have a role in maintaining the bone mass in postmenopausal women in the study of postmenopausal women with treated Addison's disease.[17] It is thus possible that the anabolic effects of testosterone on the skeleton may partly explain these results and this component of the therapy is subject to further investigation.

The increase in bone density was greater in the spine than that at the neck of the femur because the more active trabecular bone predominates in the vertebra.[18] There are several models that show such substantial reversal of bone loss, particularly in the vertebra. Treasure et al.[19] showed in a cross-sectional study that the bone loss of anorexia nervosa is reversed when menstruation returns. Greenspan[20] showed that the osteoporosis of hyperprolactinemic men with hypogondism recovers when the hyperprolactinemia is treated. Matta et al. (1988)[21] reported that the 5.9% loss of bone density after the use of buserelin for 6 months is reversed when it is discontinued. These conditions are all characterized by hypogonadism and the studies indicate

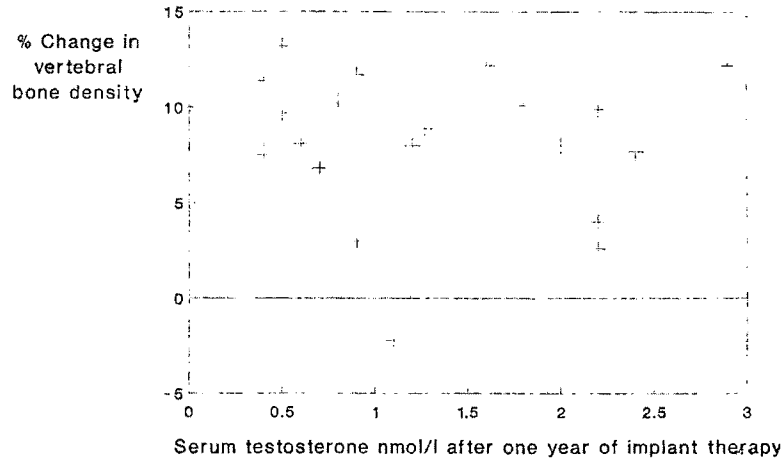

Fig. 5. Effect of serum testosterone after 1 year of therapy on percentage increase in bone density at spine.

that bone can be replaced in both men and women when plasma sex hormones return to normal physiologic levels.

The current recommended oral dosage of estrogens will suppress menopausal symptoms and prevent further bone loss but the serum estradiol and FSH levels achieved often remain in the postmenopausal range.[12] The dosage of orally administered estrogen may be limited by gastrointestinal symptoms and the liver impact on estrogen metabolism. It is probable that the safest way to achieve serum estradiol levels adequate to produce significant increases in bone mass is by the percutaneous route with either transdermal patches or subcutaneous implants.

The mechanism by which estrogen deficiency causes loss of bone remains unclear but the original Albright hypothesis of an association with a generalized loss of collagen including the collagenous matrix of the bone and the collagen of the skin is relevant. The substantial increase in vertebral spine density shown in this study can be compared with the 30% increase in skin collagen and a 25% increase in skin thickness that occurs in postmenopausal women who receive percutaneous estradiol therapy.[23] Only serial histomorphometric studies of bone biopsy specimens in these patients will reveal whether the estrogen-promoted changes in skin collagen are reproduced in the collagenous matrix of postmenopausal women.

It is reassuring from this study that estradiol and testosterone implants may not only prevent osteoporosis but will also be valuable in the older woman who might believe that it is too late to commence estrogen therapy. This therapy is also appropriate for the younger woman with premature ovarian failure who has already suffered substantial bone loss.

We gratefully acknowledge the assistance of Dereck Lowe, medical statistician, King's College Hospital, with the statistical analysis.

Fetal eye movement assessed with real-time ultrasonography: Are there rapid and slow eye movements?

Naoki Horimoto, MD, Takashi Koyanagi, MD, Shoji Satoh, MD, Toshiyuki Yoshizato, MD, and Hitoo Nakano, MD

Fukuoka, Japan

The goal of this study was to determine whether rapid eye movement and slow eye movement exist during the eye-movement period in the human fetus in utero. We studied 21 fetuses with real-time ultrasonography, 10 from 33 to 36 weeks and 11 from 37 to 41 weeks' gestation. We used the duration of eye-movement unit as a parameter and calculated the cumulative duration from the shortest to a given duration of eye movement per individual case. A scattergram of cumulative duration versus given duration obtained from all cases in each age group was analyzed with piecewise linear regression to search for a critical point(s). Critical given duration points were noted and reached statistical significance at 0.62 second and at 0.76 second during 33 to 36 and 37 to 40 weeks of gestation, respectively. These findings reveal two different types of eye movement: one with a duration of <0.6 to 0.8 second and the other with a duration of >0.6 to 0.8 second. These findings are compatible with previous criteria on rapid and slow eye movements, respectively, at 33 weeks of gestation onward. The mean value of cumulative duration at the critical point increased from 29.0% between 33 and 36 weeks to 47.1% between 37 and 41 weeks of gestation, indicating an increase in the proportionate amount of time maintaining rapid eye movement as gestation advances. (AM J OBSTET GYNECOL 1990;163:1480-4.)

Key words: Rapid eye movement, slow eye movement, human fetus, real-time ultrasonography

In 1955 Aserinsky and Kleitman[1] discovered two types of eye movements during sleep in the adult: rapid eye movements, which are characterized by rapid and jerky motions of relatively short arc, and slow eye movements, which are slow and lateral movements.

Studies have been made on eye-movement patterns in the developing human fetus by assessment with real-time ultrasonography.[2-5] However, it remains to be elucidated whether rapid-eye-movement sleep, non-rapid-eye-movement sleep, and waking states actually exist in the human fetus in utero.[6]

Slow eye movement was reported to reflect muscle hypotonia.[1] Therefore the coexistence of rapid and slow eye movements is a minimum requirement for identification of rapid-eye-movement sleep in the human fetus, as already evidenced in the neonate.[7]

Thus in this study we attempted to assess whether the two types of eye movements exist during the eye movement period in the human fetus.

Material and methods

Fetal population. Twenty-one fetuses were randomly sampled. The fetuses were divided into two age groups: 10 from 33 to 36 weeks and 11 from 37 to 41 weeks of gestation.

The week of gestation was calculated from the last menstrual period and subsequently confirmed by routine ultrasonographic examination of fetal crown-rump length at 9 to 11 weeks' gestation.[8] All fetuses were found to be within the appropriate range of birth weight for each gestational week by Japanese standards (mean ± 1.5 SD)[9] with postnatal 1-minute Apgar scores of ≥8.

All mothers were cared for in the Maternity and Perinatal Care Unit, Kyushu University Hospital, and gave informed consent to participate in the study.

Data acquisition. A real-time ultrasonography scanner (model SSA-270A, Toshiba, Tokyo) with a convex transducer of 3.75 MHz was used. With the mother in the semirecumbent position, the observational standard plane was determined to be a nearly horizontal transection of the fetal head, yielding a clear image of the fetal lens in an orbit closest to the maternal abdominal wall (Fig. 1). The lens could be identified in the form

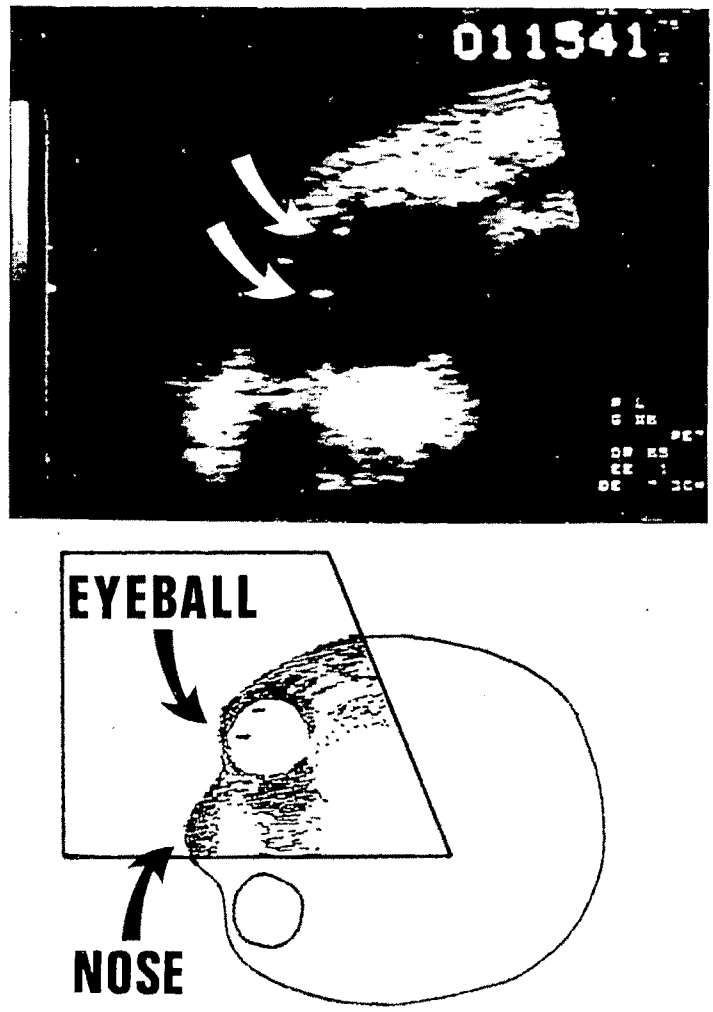

Fig. 1. Real-time ultrasonographic image for observation of fetal eye movement. *White arrows* indicate echoes originating from margins of lens. Number superimposed on right upper corner of this image indicates frame code.

of a pair of small dotted echoes, originating from both the near and the far margins of the lens, and was used as a landmark for quantifying eye movement.[2, 5] Each fetus was subjected to ultrasonographic examination only once for data acquisition in this study. An ultrasonographic image was continuously taken for 60 to 90 minutes and recorded by videotape recorder (model VO-9600, Sony, Tokyo) in real-time fashion. The frame code was simultaneously recorded on videotape with a frame-code generator (Sony model FCG-700).

Parameter definition and data processing. One unit of eye movement was defined as the movement of the lens from one stationary position through a position change to another stationary position. The eye movement period was regarded as the time sustaining the presence of movements for at least a 1-minute epoch, according to our previous reports,[5] and the eye movement period first noted after the start of the observation period was herein selected for analysis.

Data were processed on an individual case basis. While the videotapes were replayed, we determined the frame codes at the onset (F_{onset}) and the end (F_{end}) of each eye movement unit by use of slow motion and frame freezing. The duration (D) of the eye movement unit was then calculated in seconds as: $D = (F_{end} - F_{onset})/FR$, where FR is the frame rate of 29.97 frames per second.

After arranging all durations obtained in each fetus in ascending order [D_1 (shortest duration), D_2, D_3, ..., D_x (given duration), ..., D_N (longest duration)], we calculated the cumulative duration from the shortest to a given duration using the formula:

$$T_x = \left(\sum_{i=1}^{x} D_i / \sum_{i=1}^{N} D_i\right)$$

Statistical analysis. A scattergram of cumulative duration versus given duration (in logarithmic scale) was made of the data from all cases included in each age group. The scattergram was then analyzed by means

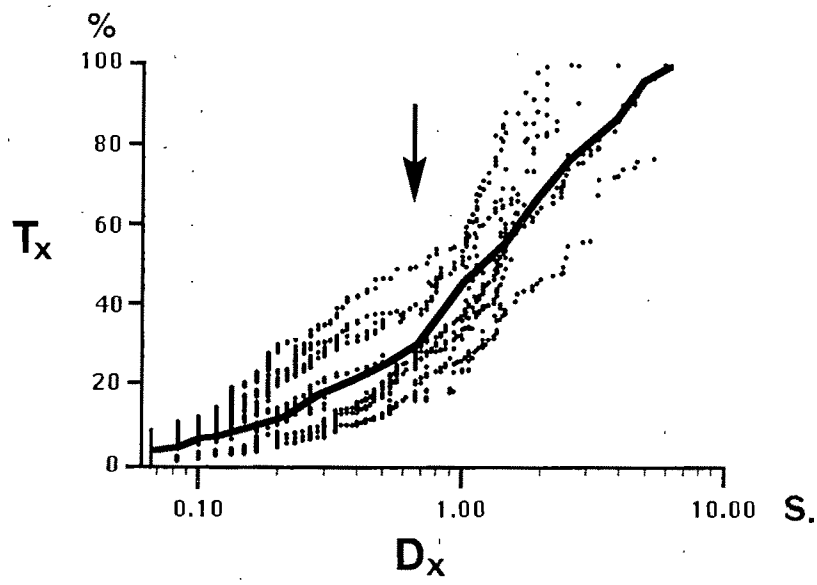

Fig. 2. Scattergram obtained from 10 cases included in 33- to 36-week gestational age group. Horizontal axis indicates duration of eye movement (D_x) in logarithmic scale, whereas vertical axis shows cumulative duration of every eye movement (T_x) by percent. *Solid line* indicates mean value of T_x. *Arrow* indicates statistically critical point.

Table I. Results obtained from piecewise linear regression analysis in both age groups

	p = 1		*p = 2*		*p = 3*

†Best critical point selected during 37 to 41 weeks' gestation.

of piecewise linear regression to search for statistically critical given duration points. For selecting the best regression equation, Mallows' Cp value is defined as $Cp = RSS/s^2 - (n - 2p)$, where n is the number of fetuses, p is the number of critical points, RSS is the residual sum of the squares from a given combination of p points, and s^2 is the residual mean square based on the regression using all given duration points.[10] The procedure for selecting the best piecewise linear regression consisted of two steps. First, p was determined as the smallest p such that the Cp value is $\leq p$; then the best combination of critical points was selected as that when the smallest Cp value was found among the groupings of critical points.[11] All calculations were made with the computer package program, BMDP9R on an IBM system 4381 (Sumare, SP, Brazil).[12]

A simulation experiment for measuring eye-movement duration. To evaluate overall accuracy of the observation system, a simulation experiment was made apart from this study (data not shown) from data acquisition, through recording of the ultrasonographic image in videotapes, replaying the videotapes and determining the frame codes at the onset and the end of each eye movement, and finally by measuring the duration of each eye movement unit. As a model for the fetal eyeball, we used a mechanical sector scannerhead (ASU-32H-3.5, Aloka, Tokyo), in which the diameter of the discoid transducer element and the scanning range resembled the size of the fetal lens and the horizontal oculomotor range in adults,[13, 14] respectively. The movement of the sector scanner transducer, submerged into deaerated water, was observed with the convex scannerhead used in the main study and was

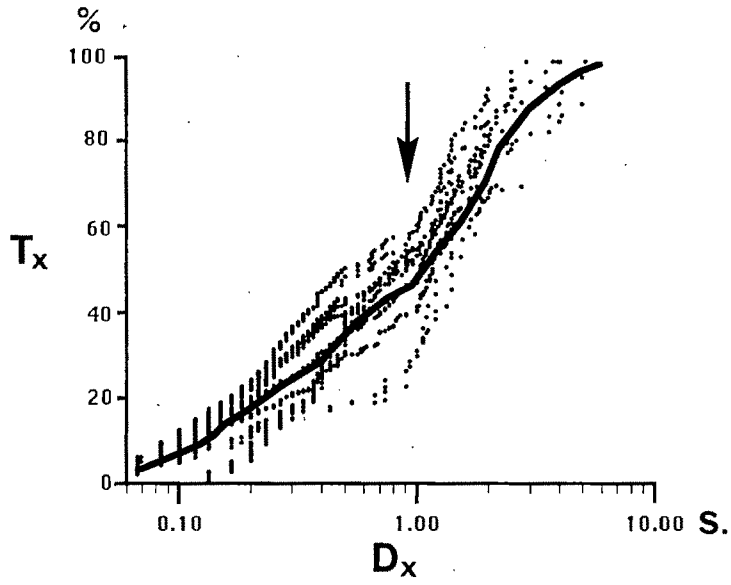

Fig. 3. Scattergram obtained from 11 cases in age group from 37 to 41 weeks' gestation. Display format and abbreviations used are described in Fig. 2.

recorded on videotape. This test was performed at two different cycles; 0.08 second and 0.09 second. Consequently, the mean values (± SE) for the two cycles were 0.08 ± 0.01 and 0.09 ± 0.01 second, and the coefficients of variation were found to be 12.5% and 11.1%, respectively.

Results

Fig. 2 shows the scattergram of the cumulative duration versus given duration in the first age group between 33 and 36 weeks' gestation. Given duration ranged from 0.07 to 4.75 seconds. One critical given duration point was indicated with statistical significance at 0.62 second (Cp = −4.53; Table I), at which the mean cumulative duration value was 29.0%.

Fig. 3 demonstrates the scattergram of cumulative duration versus given duration in the second age group at ≥37 weeks' gestation; given duration ranged from 0.07 to 5.20 seconds. One statistically critical given duration point was noted at 0.76 second (Cp = −8.20) among fetuses in this group (Table I). The mean cumulative duration value at the critical point was 47.1%.

Comment

We focused our study on fetuses at ≥33 weeks' gestation in consideration of our previous report that states that eye movements become consolidated and form a period of rapid eye movement or so-called rapid eye movement period by this point in gestation.[5] Rapid eye movement periods reach an almost uniform length of time and last approximately 30 to 40 minutes at 36 to 37 weeks of gestation onward. Taking into consideration the chronologic development of the rapid eye movement period according to advances in gestation, we divided fetuses into two age groups to document whether age-related change in the manifestation of rapid and slow eye movements is present between 33 to 36 weeks and 37 to 41 weeks of gestation.

Piecewise linear regression analysis is performed in any study to identify critical points, if any, without prior knowledge of their existence. Such analysis reveals that measurements with values ranging less than and more than critical points differ in characteristics, thus reflecting underlying factors.

From this study one critical point per age group was evident at 0.62 and 0.76 second in the duration of the eye movement unit during 33 to 36 weeks and 37 to 41 weeks of gestation, respectively, thereby indicating that two distinct kinds of eye movements exist in both age groups: one with durations from 0.07 to 0.6-0.8 second and the other with durations from 0.6-0.8 second to 4-5 seconds (Figs. 2 and 3). Our findings are compatible with those of Aserinsky and Kleitman,[1] who termed rapid and slow eye movement by the duration of such movement, in which the former lasts approximately 1 second and the latter lasts 3 to 4 seconds. Therefore the two types of eye movements we observed can be considered to correspond with the criteria of Aserinsky and Kleitman of rapid eye movement and slow eye movement. The age-related difference between 33 to 36 weeks and 37 to 41 weeks' gestation is seen by the increase in the proportionate amount of time maintaining rapid eye movement, as indicated by the increase in the cumulative duration of such movement at the critical points.

Because of the anatomic structure of the extraocular muscles attached to the orbital socket, in the absence of the supranuclear control necessary for extremely fine integration of neural activity, the extraocular muscles become hypotonic with incoordinate waxing and waning that results in the occurrence of slow eye movements.[1] Thus slow eye movements reflect decreased skeletal muscle tone, which represents the tonic phenomenon during rapid eye movement sleep, and its control mechanism differs from that of the phasic phenomenon, such as rapid eye movement. Studies have also reported that infants delivered at 33 to 35 weeks show a reduction in muscle action potentials during rapid eye movement sleep.[15, 16]

On the basis of previous reports, our findings from this study will further the determination of whether the rapid eye movement period can be linked, using rapid eye movement and slow eye movement as indicators, to rapid eye movement sleep in the human fetus in utero at 33 weeks' gestation and therafter.

We thank L. Saza for editorial support, K. Akazawa, Kyushu University, for statistical analysis, and T. Suzuki, Kyushu University, for computer assistance.

Continuous or interrupted fascial closure: A prospective evaluation of No. 1 Maxon suture in 402 gynecologic procedures

James W. Orr, Jr., MD, Pamela F. Orr, RN, Jeffrey M. Barrett, MD, John R. Ellington, Jr., MD, Ralph H. Jennings, Jr., MD, Keith B. Paredes, MD, Bruce Patsner, MD, and Dale L. Taylor, MD

Lakeland, Florida

During a 14-month period of using a long-term absorbable suture (No. 1 Maxon), 402 patients were entered into a prospective, randomized trial of fascial closure. Patients were randomized between a continuous closure (201 patients) and an interrupted en bloc (201 patients) technique. Each patient was subjected to a preoperative and intraoperative protocol for wound management. There were no acute wound failures. Wound infection rates and risk of hernia were not apparently affected by closure technique. (AM J OBSTET GYNECOL 1990;163:1485-9.)

Key words: Abdominal closure, absorbable suture

Gynecologists currently perform over 4 million operative procedures yearly in this country, 75% of which involve an abdominal incision.[1] Incision type and placement are guided by numerous variables including diagnosis, urgency, patient build, the presence or absence of previous incisions, the need for a stoma, or cosmetic preferences. To date, no prospective, randomized data concerning wound closure after gynecologic procedures exists. Therefore the selection of closure technique and suture material is usually governed by anecdotal experience, familiarity, prejudice, and previous training.

This article details a prospective evaluation of the efficacy and benefits of a nonlocking continuous, en bloc closure versus an interrupted far-far/near-near (Smead-Jones) closure in 402 gynecologic incisions using a long-term, absorbable, polyglyconate suture.

Methods and material

During the 14 months before September 1988, 404 women were entered into the study protocol. Prior approval by the Institutional Review Board of Lakeland Regional Medical Center and the Watson Clinic, Lakeland, Florida had been obtained. Each patient provided written, informed consent. The patients' risk criteria (Table I) were evaluated, and patients were eligible if their total score was <7. After entry, a computer generated randomization table was used to allocate patients into a continuous or interrupted en bloc closure technique. There was no attempt to stratify patients as to incision type because this decision was made intraoperatively. All eligible patients who consented were included in this surgical protocol.

Every patient was evaluated preoperatively by at least one of the authors (P. O.) and was examined daily during the hospital stay by at least two of the authors; 1-month and 6-month evaluations were also performed.

Surgical preparation was relatively uniform. Preoperative hospitalization was minimized and the majority (54%) of patients were admitted the day of surgery. Preoperative mechanical bowel preparation was used in all patients with a known or suspected diagnosis of malignancy. No preoperative douche was performed, and the vagina was prepped only in the operating room. If hair removal was deemed necessary, it was clipped in the operating room. All incisions were at least 15 cm in length. Single-dose antibiotic prophylaxis was routinely used; no patient received more than three doses. All vaginal cuffs were closed with 2-0 polyglycolic acid sutures. The visceral or parietal peritoneum was not routinely closed. Copious pelvic irrigation was performed before closure. Closed suction pelvic drainage was used only in patients who had radical hysterectomy and bilateral pelvic lymphadenectomy.

Fascial closure incorporated No. 1 Maxon suture (Davis & Geck, Danbury, Conn.) in all patients. Inter-

Low risk <7.

rupted closures involved an en bloc far-far/near-near (Smead-Jones) technique in vertical incisions and a wide-placed tissue "bite" in transverse incisions.[2] When an interrupted closure was used, the fascial edge to suture interface was at least 1.5 cm and the suture-to-suture distance was 1.5 to 2.0 cm. The peritoneum was only incorporated into the closure if easily mobilized. Continuous closures involved a two-suture technique, either from side to side or above and below. Sutures were placed at least 1.5 cm from the fascial edge and 1.5 to 2.0 apart. All knots were secured with at least a surgeon's-surgeon's/square-square knot. Knots were secure but not tied so as to strangulate tissue. Copious irrigation of the subcutaneous tissues was usual. Subcutaneous sutures or drains were not used. Skin clips were the chosen method of skin closure. All incisions and closures were performed by board-certified gynecologists.
